A second unrelated study concerning long-term memory, also by Appan and Browne (2012), investigated the impact of the misinformation effect on IRD. The "misinformation effect" occurs when false or misleading information is suggested to someone (e.g., a user) following the occurrence of an event and the person recalls the misinformation rather than the information he originally observed during the event. Appan and Browne (2012) demonstrated empirically the existence of the misinformation effect during IRD and extended previous findings to show that the effect exists even with factual information learned over a long period of time. The latter finding is particularly troubling for IRD, since the results show that if an analyst suggests some misinformation contrary to users' long-held beliefs or factual knowledge that they have developed through their own experiences, those users are likely to report in response to subsequent questions the information provided by the analyst (which may be arbitrary or be due to ulterior motives) rather than their own knowledge or beliefs. The potential impact of the misinformation effect on eliciting accurate user requirements and on ultimate system success is therefore of significant concern.

Beyond specific problems with long-term memory, the overall limitations on information processing mean that systems analysts, and humans in general, are not cognitively equipped to gather all possible information in any but the simplest of problems. Requirements determination is not a simple problem. Therefore, analysts employ heuristics to help them narrow the problem space. A *heuristic* is a short-cut, or rule-of-thumb, for achieving satisfactory (and perhaps better) results in solving a problem (Simon 1996). People evolve heuristics for solving problems based on experience; the more experience a person has with a type of problem, the better his heuristics typically are. Heuristics allow humans to circumvent their cognitive limitations, particularly those associated with working memory, but they come at a cost. Because they are not optimization techniques (people do not gather all available information and do not integrate it optimally), heuristics result in errors (Tversky and Kahneman 1974). Some of the errors created are random and some are systematic. The systematic errors are usually referred to as cognitive biases. A *bias* is a systematic deviation from an accurate answer; accuracy in this case can mean normatively accurate information or a target standard resulting from consensus.

In the elicitation of requirements from users, numerous biases have been theorized and several have been investigated empirically. Basic issues in cognitive biases in requirements determination have been discussed by Browne and Ramesh (2002), Ralph (2011), and Stacy and MacMillan (1996). Prompting strategies for overcoming cognitive biases in requirements elicitation have been suggested by Browne and Rogich (2001), and a list of cognitive biases and strategies for overcoming them is provided in Pitts and Browne (2007).

The influence of cognitive biases on human behavior, including requirements elicitation, is extensive, and a full discussion is beyond the scope of this chapter. It is known that people are affected by the ease with which information can be recalled, by insensitivity to base rates (i.e., the actual rate of occurrence of events in populations), by vividness of stimuli, by giving inappropriate weight to small samples, by misconceptions of chance events (e.g., believing that certain patterns in data cannot occur without a causal explanation), by seeking primarily confirmatory evidence for conclusions, by anchoring on initial values (or existing procedures), and by overwhelming overconfidence, among many other biases (see, e.g., Bazerman and Moore 2013; Kahneman 2011). These biases all impact the information elicited in requirements determination as they affect both the users and the analysts. As one example, important research concerning the anchoring bias in requirements modeling has been performed by Parsons and Saunders (2004) and Allen and Parsons (2010) and in requirements elicitation by Jayanth et al. (2011). The interested reader is referred generally to Bazerman and Moore (2013) and Kahneman (2011) and, for examples specific to IRD and systems development, to Browne and Ramesh (2002) and Stacy and MacMillan (1996). In general, the study of cognitive biases is an under-researched area in the information systems field.

A second type of bias that affects IRD is motivational biases. Motivational biases result from perceived incentives in the decision-making environment or from internal desires or preferences (see Bazerman and Moore 2013 for a general discussion). Examples of motivational biases include self-serving attributions (i.e., taking credit for successes and blaming failures on external sources beyond the person's control), reporting false facts or beliefs to curry the favor of influential others (e.g., bosses), the illusion of control (i.e., the belief that one can control random events), real and anticipated regret, and deliberately escalating commitment to a failing project. A large body of literature in the information systems discipline concerning escalation of commitment has been developed by Keil (1995) and Mähring and Keil (2008). Most other motivational biases have not received attention, however. Motivational biases generally (although not universally) arise in IRD because requirements determination involves numerous parties in a social process, and both analysts and users are motivated to portray themselves in a positive light, to hide errors, and to avoid blame.

27.2.2 Group Level Principles

When analysts elicit requirements from users, the parties are engaged in a social process. In addition to the motivational biases just discussed, social influence concerns such as conformity, persuasion, and

trying to please the analyst (the "demand effect" or "getting along effect") all are potential problems for the analyst gathering requirements (see Cialdini and Trost 1998). The process of IRD should not involve the analyst imposing his will on the user or attempting to persuade him to agree to certain requirements (Alvarez 2002). The process should be one of open inquiry, in which the analyst attempts to gain an accurate understanding of the user's needs. Thus, the analyst should approach the process with an open mind, ignoring pre-conceived notions about what the user may want or need and without thinking ahead to implementation details. The analyst should be aware that his role typically gives him a type of perceived legitimate power over the user (Alvarez 2002; Tan 1994), which may lead the user to attempt to subtly assess what the analyst wants and then report or agree to those "requirements" to conform and/or to try to please the analyst. In such cases, the analyst may be pleased, but the requirements provided are likely to be less accurate than desired.

When IRD occurs in group settings, in information systems development, the interactions are typically organized as joint application development, or JAD, sessions (Liou and Chen 1994). JAD sessions are requirements determination sessions involving one or more analysts, several or many users, and often additional stakeholders in the system (Dennis et al. 1999). In such cases, in addition to the individual issues involved, analysts must be aware of group dynamics. Issues such as company politics, power and hierarchy (e.g., Milne and Maiden 2012), impression management, attempts at ingratiation, coalitions, group polarization, illusions of agreement (e.g., groupthink), conformity, roles, and norms in the organization all must be taken into account (see, e.g., Guinan et al. 1998). Analysts are often poorly prepared to manage group dynamics, and skilled meeting facilitators are often employed to ensure that the purpose of the session, that is, requirements for the system, is adequately met.

A major difficulty that arises because the asking strategy in IRD is a social process is communication issues between analysts and users (Davern et al. 2012). Much research has investigated communication issues (e.g., Bostrom 1989; Davis et al. 2006; Valusek and Fryback 1985). Attempts to overcome or mitigate user-analyst communication issues have been made, particularly by increasing user participation in the systems development process. However, the impact of user participation has been mixed in empirical studies (e.g., Gallivan and Keil 2003; Hunton and Beller 1997; McKeen et al. 1994), and further research is necessary to determine the amount and type of user participation that can result in the best requirements determination results.

27.2.3 Examination of Internal and External Documentation

As noted, a second method usually used to accompany the asking strategy is for the analyst to examine internal and external documents (e.g., Davis 1982; Kotonya and Summerville 1998; Maiden and Rugg 1996). Analysts must decide which documents contain valuable and relevant information for the firm and for the users and should be incorporated into the proposed information system and which documents are redundant, not used, or not valuable and should be omitted (Robertson and Robertson 2006; Watson and Frolick 1993). For example, Watson and Frolick (1993) discussed requirements determination for executive information systems and noted the importance of examining memos, e-mails, and various internal company documents as well as external documents such as articles, books, marketing research information, and government and industry publications. Company forms and reports often determine the desired inputs and outputs, respectively, of systems and are therefore a natural starting point for analysts. However, with all existing documents, analysts must be concerned about improper anchoring on current data and processes (Davis 1982). Simply because internal documentation exists or external data seem to support requirements does not mean they should be included in the system (Robertson and Robertson 2006). Because people prefer concrete examples to abstract concepts, there is a strong temptation to utilize an existing document, design, interface, etc. as a starting point. This initial anchoring point, however, typically precludes other classes of potential alternatives, including more innovative ideas. Oftentimes, business process reengineering using outside experts (with no

pre-conceived notions or company "baggage") may be required to be certain that existing documentation reflects requirements that are useful and appropriate for the system currently under design.

27.2.4 Observation of Users and Organizational Task Performance

Observation of users as they perform organizational tasks is also an important method for eliciting requirements (Alvarez 2002; Byrd et al. 1992; Kendall and Kendall 2010; Leifer et al. 1994; Robertson and Robertson 2006). Users often have difficulty verbalizing how they perform their everyday tasks. As experience increases, people typically lose conscious access to the steps they take in performing a task (Leifer et al. 1994; Simon 1979). Observation can help analysts either as a first step in understanding work processes or in filling in gaps in user descriptions of how they perform their jobs (Kendall and Kendall 2010). Observation can be performed either silently or interactively. Silent observation requires the analyst to observe the user performing his task without interruption. The advantage of this method is that the user's typical behaviors are not (ideally) altered because of interruptions. The main disadvantage of this method is that the analyst can observe only behavior, not cognition, and therefore may not understand how or why an action is being performed. Interactive observation permits the analyst to interrupt the user's task performance when an action or the reasons for it are not clear (Robertson and Robertson 2006). This allows the analyst to understand how and why the action is being performed, assuming the user can articulate the reasons. The main disadvantage is that the user's behavior and thought processes are interrupted, which may lead to task performance that is not typical. This could cause the analyst to model the requirements inappropriately. Based on the strengths and weaknesses of the two techniques, using silent observation first and following that technique with interactive observation may be the best approach.

A disadvantage of observation generally is the Hawthorne effect, in which users act differently because they know they are being observed (Parsons 1992). There is no perfect cure for the Hawthorne effect, but analysts should assure users that they are not being judged and that the results of their individual task performance will not be reported (only aggregated results), if true. If the organization is unwilling to promise anonymity for individual performance, it is recommended that the analyst utilize a different technique.

Another method for observing task performance is through protocol analysis (Byrd et al. 1992; Ericsson and Simon 1993). Protocol analysis requires users to think aloud while they perform a task, and their thoughts (sometimes accompanied by movements) are recorded on tape, video, or digital media. The resulting vocalized thoughts can be analyzed to trace task performance and to capture certain aspects of behavior and cognition that both silent and interactive observation may miss. When the correct procedures are utilized, results from protocol analysis can be valid and highly valuable sources of information (see Ericsson and Simon 1993).

27.3 Impact on Practice

Requirements determination is arguably the principal job of systems analysts. Regardless of whether the proposed system is intended to automate or provide decision support for an existing manual system, upgrade an existing computerized information system, or tailor a purchased ("off-the-shelf") software program for a company's needs, user and organizational requirements must be determined. Because information systems are now the lifeblood of organizations (and, increasingly, individuals), requirements determination is a critical and ubiquitous activity in companies today. Thus, all of the issues discussed in the previous section are important and relevant for IRD practice.

Faulty requirements are generally thought to be the most common cause of information system failure in organizations (Bostrom 1989; Byrd et al. 1992; Hofmann and Lehner 2001; Wetherbe 1991). Underutilization, in which systems are used but not to their full functionality, is also a problem that results from inaccurate or incomplete requirements. The cost of information systems failures to businesses is

estimated in the hundreds of billions or even trillions of dollars worldwide each year.* Thus, the impact of improving information systems on organizational performance is difficult to overestimate.

Requirements determination research over the years has directly influenced systems analysis practice. For instance, analysts are now trained in multiple elicitation techniques and are often warned about the influence of various problems in elicitation (Kendall and Kendall 2010). For example, analysts ideally should provide little input during early stages of the interview process, stimulating the user to talk and probing using only neutral questions. This allows the user to express his views without any priming or undue influence from the analyst. At later stages of the process, the analyst can probe to elicit specific knowledge not yet revealed (Appan and Browne 2012).

Research demonstrating the advantages of involving many stakeholders and multiple points of view has led to the use of JAD sessions, noted earlier. JAD sessions allow for informed discussion of various potential needs both between users and analysts and between users themselves. The assignment of devil's advocates in JAD sessions to improve and polish ideas is also a result of research on group decision making (see Browne and Ramesh 2002). Although JAD sessions have weaknesses, such as wasted time during group brainstorming (Brown and Paulus 2002; see also Sandberg 2006), they bring significant strengths to the IRD process, including user involvement and increased "buy-in" by stakeholders (Davidson 1999).

One practical implication of research in IRD that has yet to appear on a large-scale basis is training analysts to recognize the heuristics they use and the biases and other cognitive challenges to which they are subject. Articles in the practitioner literature have appeared (e.g., Stacy and MacMillan 1996; West 2008), but they have not been widespread and there is no evidence of systematic training. Such training has the potential to make a profound contribution to the effectiveness and efficiency of requirements elicitation, perhaps more than any other set of findings from the research literature. Motivational issues are also critical, but they are generally more easily recognized and remedied. Cognitive biases, recall issues, attentional deficits, and other cognitive problems operate primarily subconsciously and are largely hidden from view. This makes their effects particularly pernicious and difficult to discern.

As noted in the *Underlying Principles* section mentioned earlier, there are differences in requirements determination in the SDLC approach and agile approaches to systems development. In the SDLC, requirements are gathered primarily in one of the earliest stages of the process. After they are modeled and verified, users often "sign off" on the requirements, and system designers then proceed with development of the system. There are feedback loops in the SDLC, and analysts and designers often must return to users for additional requirements and/or clarifications. However, the initial stage subsumes the majority of the requirements determination effort. Research has demonstrated that one of the weaknesses of this approach is that users often do not know what they need during the early stages of the development of a system (especially a new system) and that their "sign off" is of dubious validity (Wetherbe 1991). Additionally, analysts may not understand the proposed system well enough to ask appropriate questions at this point, resulting in an inadequate determination of requirements (Davis 1982). A second weakness is that requirements often change during development (e.g., Maruping et al. 2009), and the "frozen" requirements document with which designers work when using the SDLC can therefore make the resulting system inappropriate or out of date by the time it is completed. These findings led to the agile methods discussed earlier, including such methods as scrum and extreme programming, which rely on short bursts of IRD followed by mock-ups or prototypes to which users can quickly react. It is likely that such agile methods will continue to be used and perhaps increase in popularity as the techniques are improved and the advantages, particularly quick user feedback, are fully utilized. It is unlikely, however, that an initial requirements gathering will disappear from agile methods that survive. Absent an initial substantial investment in requirements elicitation, the first prototypes will reflect what

* For one estimate in the trillions of dollars, and a critique of that number, see http://www.zdnet.com/blog/projectfailures/worldwide-cost-of-it-failure-62-trillion/7627?tag=content;siu-container and http://brucefwebster.com/2009/12/28/the-sessions-paper-an-analytical-critique/.

the analyst thinks he knows about the system or what he thinks should be included. There is no more fertile ground for the types of cognitive and motivational biases and other problems discussed in this chapter than this type of approach to systems development.

27.4 Research Issues

Despite the large body of research that has developed concerning requirements determination over the past 30 years, there is no shortage of work remaining. Because the activity involves individual and group behavior, and all the cognitive and motivational issues associated with such behavior, IRD progresses and improves largely as our understanding of human behavior progresses in the social sciences. This section describes a limited subset of research issues that are currently of interest in the field or will be important in the near future.

One important set of issues is the enduring topic of cognition in IRD. As we gain a better understanding of judgment and reasoning, and how decisions are made, we can improve the efficiency of IRD and elicit and model requirements more accurately. This process includes a better understanding of how analysts allocate their attention, how they reason and make judgments and choices, and what information they commit to long-term memory. Additionally, the recall of information from long-term memory, and the problems that have been shown to occur, remain issues that deserve further research. As noted in the *Underlying Principles* section in the preceding text, recent research in the information systems field has addressed some of these issues. In addition, neuroscience techniques such as functional magnetic resonance imaging and electroencephalography are allowing information systems researchers to develop an understanding of the brain at the neural level (e.g., Dimoka et al. 2011) that will aid immeasurably in our understanding of cognition and behavior in IS development.

A related concern is the issue of eliciting requirements that help analysts directly with decision making. Decisions about requirements require reasoning, judgment, and choices by systems analysts, and the direct elicitation of user preferences about requirements can aid immeasurably in these decisions. Some research in IRD has addressed direct elicitation of user preferences (e.g., Liaskos et al. 2011) and decision making more generally (e.g., Alenljung and Persson 2008). However, much more research from decision theory could be incorporated to improve these outcomes. Preference elicitation, probability elicitation, and many other decision analytic techniques can be incorporated in IRD to provide a stronger foundation for the choice and prioritization of requirements by analysts (see, e.g., Goodwin and Wright 2004; Jain et al. 1991; Keeney and Raiffa 1993; von Winterfeldt and Edwards 1986).

Another important issue for systems analysts in IRD is when to stop eliciting and modeling requirements. In unstructured problems with nearly limitless information, such as IRD, analysts can conceivably elicit information and model requirements indefinitely. However, time, cost, cognitive, and motivational considerations prevent them from doing so. Research has revealed that analysts (unsurprisingly) do not gather all available information in requirements elicitation settings and has demonstrated cognitive stopping rules that analysts employ to cease requirements determination efforts (Browne and Pitts 2004; Pitts and Browne 2004). Additional research has investigated stopping rules in information search behavior more generally (Browne et al. 2007). Stopping rules are particularly important in IRD because of the costs of underacquisition and overacquisition of information. Overacquisition results in wasted time and money and may lead to unnecessary features in software. Underacquisition results in underspecified requirements, leading to systems that likely do not meet user needs. Much additional work is necessary to understand both cognitive and motivational reasons that analysts stop during all activities in IRD, including elicitation, representation, and verification of requirements.

In addition to basic cognitive issues, an improved understanding of analysts' use of heuristics and the biases that result can have a profound impact on IRD. As noted earlier, human decision making is often biased in predictable ways. Both analysts and users are biased in their provision and interpretation of information and in the decisions they make based on that information. Therefore, an improved understanding of the conscious and subconscious heuristics that analysts use to elicit, model, and verify

information, and of the biases that are present in both analysts and users, has the potential to improve IRD and the remainder of the systems development process significantly.

Another important issue is that software development is increasingly performed by people who are not colocated geographically. This means that requirements determination must be performed by people in different places, perhaps of different cultures, who likely have never met. The telecommunications challenges of such interactions have largely been solved, but the lack of face-to-face communication may have significant impacts on the process and outcomes of IRD. Research in communication theory and organizational behavior has demonstrated the differences between face-to-face communication, computer-mediated communication, and other forms of communication. Although some excellent research concerning IRD has been performed both in this area and the related area of off-shoring (e.g., Aranda et al. 2010; Dibbern et al. 2008; Evaristo et al. 2005), much more work is necessary to understand the full implications of distributed requirements determination.

Another important future research issue concerns requirements determination for purchased software. Much software is now purchased rather than produced “in-house,” and requirements determination can be a complicated process with such software. Ideally, requirements are determined before software is purchased to ensure that the software meets user needs. However, software can be purchased for a variety of reasons that are unrelated to requirements, including political reasons, purchasing from a vendor with which the company already has a relationship, better pricing, etc. If requirements are determined beforehand, systems analysts and designers will still need to integrate the system into the company’s environment. If requirements are not determined a priori, or if only a cursory attempt is made, the challenges upon the arrival of the software can be daunting. Analysts will need to determine user requirements and then assess how (and if) the software can be tailored to those requirements. Some research has addressed these issues (e.g., Parthasarathy and Ramachandran 2008). However, as software is increasingly purchased off-the-shelf or in large-scale company-wide packages (e.g., enterprise resource planning systems), analysts’ challenges in determining requirements escalate dramatically. In such cases, arguments have been made that it is easier to change user processes rather than the software (e.g., Davenport 1998; but for a contrary view, see Hong and Kim 2002). In many cases, dramatic IT implementation failures have resulted from systems that could not be properly adapted to company requirements after purchase (see, e.g., Chen et al. 2009). More research is needed to help analysts manage the challenges associated with IRD in these contexts.

Another important research question concerns how users can be trained and motivated to provide better and more complete requirements. Users are the domain content experts in most systems development efforts, and systems analysts (and the organization) rely on them to provide requirements that will lead to successful systems. However, users suffer from the same biases as analysts. There is also often inertia among users who do not want to change how they perform work, which is nearly inevitable with the introduction of a new information system (Gallivan and Keil 2003; Markus and Benjamin 1997). Thus, users may not provide necessary information or may deliberately introduce misinformation (Appan and Browne 2012). Additional research investigating requirements elicitation issues from the user side would be highly valuable.

Specific content areas are also important. Although most research has focused on methods and tools for IRD that can be generalized across content domains, some tailoring is often necessary depending on the domain. For example, Schneider et al. (2012) note that many systems are now security-related, and requirements determination expertise for such systems is often lacking. They state that “Identifying security-relevant requirements is labor-intensive and error-prone” (p. 35) and suggest organizational learning tools to aid analysts in determining requirements for security-related software. Similarly, Vivas et al. (2011) point out the difficulties in designing security-related systems that ensure privacy, trust, and identity management. Fabian et al. (2010) provide a conceptual framework for understanding requirements elicitation for security-related applications. Considering the continuing threat to system security, further research into this content area, with methods and tools for appropriately determining system requirements, is crucial. Other content areas may similarly benefit from IRD research directed specifically toward them.

Convincing practitioners to use the methods and tools suggested by research is another topic worthy of further investigation. Sikora et al. (2012) point out that many methods generated by academics and supported by empirical research do not make their way into common usage among systems analysts. The authors attribute this adoption problem in part to a lack of understanding among academics concerning the tools practitioners need (ironically, perhaps, a requirements determination problem), but a lack of reading of the research literature and general suspicion of academics by practitioners also likely play a role. Better dissemination of research results and better connections with practicing systems analysts by academics have the potential to improve this situation, but more research into the full nature and causes of the problem would be useful.

Requirements determination is a critical and enduring topic in systems development. Many other issues are important for research, and the discussion in this section should be considered a starting point for topics worthy of investigation.

27.5 Summary

IRD is central to systems development because it occurs early in the process and directly influences all activities that follow it. Much research has been performed in the area, but because it is critical to all systems development it is an enduring research topic in computer information systems. Both successes and difficulties in eliciting requirements have been discussed in this chapter, as well as methods for mitigating the problems that occur. IS practice is directly impacted by research in the area because systems analysts are always gathering requirements and are under increasing competitive pressure to produce systems quickly with appropriate, and often innovative, features. Excellent requirements determination is like creative problem solving, with innovations flowing directly from requirements users may not have even imagined before talking with a systems analyst. Needless to say, technology is ubiquitous throughout world societies today. Technology directly improves productivity and standards of living. Advancements and innovations in technology can only be achieved through an improved understanding of users' needs and desires and through the proper management of these requirements during the entire systems development process.

From Waterfall to Agile: A Review of Approaches to Systems Analysis and Design

Joey F. George
Iowa State University

28.1 Introduction

While there will always be some debate about when and where the first information system for business was developed, it is generally agreed that the first such system in the United Kingdom was developed at J. Lyons & Sons. In the United States, the first administrative information system was General Electric's payroll system, developed in 1954. Now, 60 years later, the people who designed and built those systems would scarcely recognize the approaches and tools currently used to develop information systems. Systems development, which will be used in this chapter synonymously with systems analysis and design, has changed quite a bit in the past six decades.

It is the premise of this chapter that systems development has evolved through three distinct phases (Figure 28.1). Initially, development was a craft, where each system was unique and not replicable. Changes in technology and in attitude, and concerns from organizational management, led to the second phase, where development was seen as a feat of engineering. Planning, structure, and documentation governed the process. But, according to critics, the approach grew too big, too rigid, and too slow. New approaches began to emerge, including the rational unified process (RUP) and participatory design. Eventually, a new phase dawned, and the focus shifted from plan-based to small, fast, and agile. Today, the plan-based and agile approaches coexist side-by-side. This coexistence is not tension free, however, and this uneasy state of affairs will no doubt be followed by another phase, although what

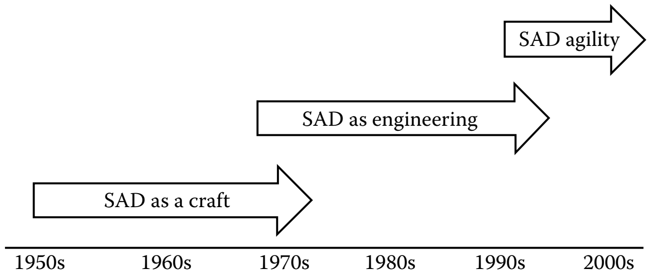

FIGURE 28.1 Three phases of systems development approaches.

that will be is not so clear. In this chapter, we will present an overview of the three phases of systems development approaches, and we will close with some conjecture on what the next step might be. Each phase will be presented with reference to specific methodologies and tools that emerged during that phase, but in each case, the list is only representative and not comprehensive. A complete list of all of the development methodologies that have been created and used in the past 60 years is far beyond the scope of this chapter.

28.2 Systems Development as Craft

In the early years, especially in the time before early third-generation languages such as COBOL, software development more closely resembled an art form than a production business process. Early systems development often occurred in a chaotic and haphazard manner, depending on the skills and experience of the people performing the work (Green and DiCaterino, 1988). In this era, developers were technically trained to work on particular hardware systems, which were incompatible with systems manufactured by other vendors. Many capitalized on peculiarities of a particular machine, using their proprietary machine and assembly languages, for writing and optimizing code. Developers had little understanding of the business, and user needs were poorly understood, if considered at all. There were no development methodologies. "The approach programmers took to development was typically individualistic, often resulting in poor control and management of projects" (Avison and Fitzgerald, 2003, p. 79). Schedules, budgets, and functionality were all unpredictable, and maintenance was a nightmare, as documentation was largely non-existent. When the system designer left the firm, few of those remaining had clear ideas about how to maintain the systems left behind. As technology improved, with the development of procedural programming languages, database management systems, and as management grew tired of the chaos and waste, this era started to come to an end. Calls for structured programming (Dijkstra, 1968) were accompanied by calls for a more structured and predictable approach to systems development.

28.3 Systems Development as Engineering

The structured approach emerged in the 1970s and continued to dominate systems development well into the 1990s. At the heart of the structured approach was a focus on designing and building systems the same way other artifacts, such as bridges and buildings, are designed and built. Like these artifacts, systems would start as concepts, which would then be modeled using several different tools, and these logical models would be converted to physical plans that would guide the construction of the system. The overall process would become an engineering process, and systems developers would become software engineers. Development would become systematic, predictable, repetitive and repeatable, measurable, heavily documented, and reliable. As a result, the productivity of programmers and developers would increase, as would the quality of the resulting systems.

Although many have been associated with it, maybe the best known advocate for the structured approach was Edward Yourdon. Yourdon (1989, p. 3) listed the major components of the structured approach as:

> *Structured analysis*: A collection of graphical modeling tools that allows the systems analyst to replace the classical functional specification (text based) with a model that the users can actually understand….
>
> *Top-down design and implementation*: The strategy of designing a system by breaking it into major functions, and then breaking those into smaller subfunctions, and so on, until the eventual implementation can be expressed in terms of program statements.
>
> *Structured design*: A set of guidelines and techniques to help the designer distinguish between "good" and "bad" designs. Proper use of structured design will lead to a system composed of small, highly independent modules, each of which is responsible for carrying out one small single-purpose function.
>
> *Structured programming*: An approach to programming that constructs all program logic from combinations of three basic forms (sequence, loops, and conditional statements).

The graphical models that structured analysis relied on included data flow diagrams and entity relationship diagrams. Structured design relied on tools such as structure charts and on concepts such as modularization, coupling, and cohesion. Structured programming made use of flow charts and decision tables. Despite the intuitive appeal of bringing order to chaos that structured analysis and design promised, adoption by organizational software development groups was generally slow (Fichman and Kemerer, 1993). For many, it was difficult to accept discipline where it had been missing before. The learning curve for mastering the many diagrams and other tools that supported structured analysis and design was substantial.

28.3.1 Systems Development Life Cycle

At the core of structured analysis and design was the systems development life cycle (SDLC). The SDLC embodies the key ideas of any product life cycle. At some point, a need is recognized; the need is investigated and a solution is designed, built, and released. Eventually, the solution reaches its maximum usefulness and begins to decline. Eventually, it must be replaced and a new solution must be created. One cycle has ended and a new one begins.

Although no two people in the IS field, either academics or practitioners, seem to agree about the exact form and contents of the SDLC, it does constitute a useful model of the systems development process. Figure 28.2 shows a generic SDLC model, typically referred to as a waterfall model.

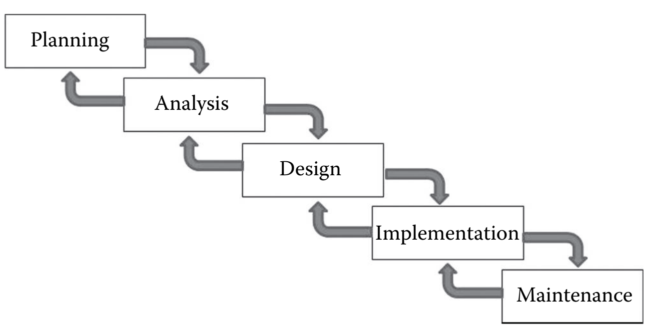

FIGURE 28.2 A waterfall systems development life cycle.

Although different versions of the waterfall SDLC have different numbers of phases, the generic model here has five phases that capture the basic structure of the systems development process. The first phase, planning, represents all of the activities that result in the identification of a need for a system. Once the need is recognized, it is important to gain a clear understanding of the problem or opportunity that sparked the need. The existing system should be analyzed, and any additional requirements should be determined in this phase, analysis. Useful tools for analysis include joint application design (JAD) and prototyping (explained in more detail later in this chapter). Once the existing situation is understood, it can be compared to where things should or ought to be. At that point, a solution can be designed, and this is what occurs in the design phase. Design involves both high-level logical design and physical design tied to a particular computing platform and operating environment. Once designed, the solution can be constructed, tested, and installed or released, the primary activities of implementation. Once the solution has been installed in an organization, the maintenance phase begins. In maintenance, the work centers on keeping the solution viable, including making any changes required due to the changing business environment and changing regulations and legal conditions. In maintenance, programmers also work to correct errors in the system and to optimize system performance. At some point, the solution is no longer viable and a new solution must be sought, ending one cycle and beginning another.

The end of each phase is a major development project milestone. As a phase ends, a decision must be made to stop or to continue. If the decision is made to continue, the next phase can begin. Notice that there are two sets of arrows connecting the phases in Figure 28.2. One set goes downhill, connecting the phases in the order in which they were described previously. Yet, the systems development process is rarely this cleanly structured. Early waterfall models contained only the downhill set of arrows, and this was the source of much early criticism of the model. In practice, it is much more typical for developers to repeat a phase, or to return to an earlier phase, as system requirements change and as work completed earlier needs to be reexamined or even redone. Iterations within the life cycle are very common. The second set of arrows, the ones going backward and uphill, has been included in Figure 28.2 to represent the possibility and likelihood of iterations within the life cycle. The flow of work is not linear, as would be the case in a true waterfall, but instead it is cyclical. The uphill arrows allow the work flow to move from one phase to an earlier phase, and in conjunction with the downhill arrows, allow for numerous iterations between phases.

The name waterfall refers to the shape of the model, in that the work flow cascades from one phase down to the next until the end is reached. As indicated previously, there are many variations of the standard waterfall SDLC. Techniques such as rapid application development (RAD) (Martin, 1991) used modified versions of the waterfall SDLC. RAD will be discussed in a later section.

Another way to visualize the SDLC is the spiral model (see Boehm, 1988), shown in Figure 28.3. The spiral model is also referred to as an evolutionary model. The spiral model combines the iterative nature of development with the systematic, stepwise approach of the waterfall model. Software is seen as being developed in a series of incremental releases. Early releases might be prototypes, but increasingly, the versions of the software developed are more complete. As more complete versions of the software are released, what was conceptualized as maintenance in the waterfall model is conceptualized here as subsequent passes around the spiral.

According to the model in Figure 28.3, each pass around the spiral, whether for initial iterative development or for later maintenance, moves through six different tasks (Pressman, 1997). The first is customer communication, which involves establishing effective communication between the developer and the customer or user. The second task is planning, where resources, time-lines, and other project information is defined. The third task is risk assessment. Here, technical and management risks are assessed, and if the risks are too high, the project can be ended at the go-no-go axis. The fourth task is engineering, which represents the building of the software application. Engineering corresponds to design in the waterfall model. The fifth task is construction and release, which contains many of the same activities as were included in the implementation phase earlier: construction, testing, installation, and providing

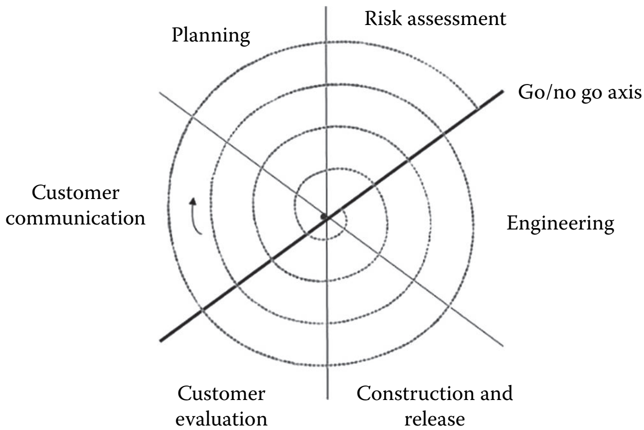

FIGURE 28.3 A spiral systems development life cycle.

user support. The sixth task is customer evaluation. The evaluation process elicits feedback on the engineering and construction and release tasks.

While the waterfall model is a simple and easy to understand representation of the systems development process, the spiral model presents a more complex and hence more realistic view. The spiral model adds iteration, risk assessment, and a more sophisticated view of maintenance to the basic waterfall model. Many of the basic tasks central to system development are the same in both models, however, as would be expected. The spiral model has also had great success in practice. Boehm (1988) cites adherence to the model as the cause of productivity improvements as high as 50% in development projects at TRW (an aerospace and automotive company, purchased by Northrop Grumman in 2002), where Boehm's particular version of the model was developed and used. The spiral model is not suited to all software development efforts, however. It best fits large-scale development projects. Another limitation in practice is its demands for considerable risk assessment expertise in order to succeed, an issue of particular concern to both Boehm and Pressman.

28.3.2 Structured Tools and Techniques

As the structured approach to systems development became more widely adopted, various tools and techniques were developed to enrich the approach and to make it easier to follow. People began to automate the graphical tools that supported the approach, and eventually the automated tools were combined with a rigorous methodology in computer-assisted software engineering, or CASE, tools. Others borrowed techniques from engineering, such as prototyping, where a smaller working model of an artifact was built as a way to help system users articulate the system's requirements. Other techniques created to assist the requirements determination process included JAD, a method that brought together the key stakeholders (or their representatives) in one place at one time, to help clarify what was desired in the new or revamped system. Each of these tools and techniques, all of which strongly supported the structured approach to systems development, will be discussed in more detail in the paragraphs that follow.

CASE tools were developed as a way to use the power of information technology to support the software development process. CASE tools are bundles of software tools that make analysis, design, documentation, and coding consistent, complete, and easier to accomplish. CASE packages built for the structured approach included tools for creating and maintaining data flow diagrams, entity-relationship diagrams, and structure charts, among others. The diagramming tools were linked in that each object created in one of the tools was entered into the central repository around which the CASE product was built. The repository stored data about all of the different elements that make up the system analysis

and design. CASE tools typically also contained facilities that allowed for screen and report design, as well as facilities that generated database structures and program code. Many structured CASE tools also allowed checking for consistency, completeness, and design errors.

Although structured CASE tools were expensive, costing several thousand dollars per copy, including training and support, they were generally believed to increase developer productivity. A case study of the implementation of Texas Instruments' information engineering facility (IEF) at a British firm in 1989–1990 reported productivity improvements of 85% and system delivery rate increases of around 200% (Finlay and Mitchell, 1994). Developers who used structured CASE were more likely to follow a structured systems development methodology than their counterparts who did not use CASE (Lending and Chervany, 1998). However, given the high cost and steep learning curve, relatively few firms adopted structured CASE tools, and for those that did, relatively few of the developers used CASE (Iivari, 1996; Lending and Chervany, 1998). Where CASE tools were adopted, there was strong management support for the approach, the tools were perceived as having relative advantage over non-CASE methods, and use tended to be mandated, not voluntary (Iivari, 1996).

Prototyping was a process borrowed from engineering, in which a scale model of an object or system was developed, both as a test-of-concept and as a device to facilitate communication between designer and client (Gavurin, 1991; Naumann and Jenkins, 1982). The software tools used for prototyping could be as simple as paint programs or as complex as CASE tools that allowed users to enter data and navigate between screens. The main idea behind prototyping as a technique was the provision of a means by which developers could transform user requirements into objects that users could see, touch, and use. Users could then provide feedback to developers about the prototype, about what worked and what did not, and about what else they would have liked to see. The developer would then take that feedback and use it to modify the prototype, beginning another round of iteration between user and developer. At some point, it was decided to either keep the prototype as the basis for the production system (evolutionary prototyping) or to throw it away (sometimes called mock-up design prototyping), while using the knowledge gained in the prototyping process to construct the production system. Prototyping became very popular in system development efforts, with over 70% of firms surveyed reporting the adoption of prototyping by 1995 (Hardgrave, 1995). Studies of prototyping revealed that, compared to an SDLC approach that did not use it, prototyping was associated with higher levels of both user and developer satisfaction, higher levels of user commitment, improved communication with users, earlier detection of errors, better code, and improvements in the development process in terms of shorter development time and less effort for developers (Beyton-Davies et al., 1999; Cerpa and Verner, 1996; Mahmood, 1987). By its very nature, prototyping encouraged meaningful and frequent interaction between user and developer. Prototyping was not without problems, however. Prototyping was associated with difficulties in managing user expectations, enticing users to commit to fully participate in the prototyping effort, and with project management generally (Beyton-Davies et al., 1999).

JAD was a technique developed primarily to address the issues involved in determining user requirements for a system (Wood and Silver, 1995). Traditionally, a developer determined requirements by interviewing users, studying existing systems, perusing input form, reports, and other documents, and observing users while working. User interviews were an important source of information for what the system being developed should do and look like. Interviews, however, were difficult to schedule, as users had their own regular work to complete while assisting the developer. Contradictions between users also had to be reconciled, which required follow-up interviews. The process could be very time consuming and frustrating.

JAD was developed to deal with the difficulties in scheduling interviews and reconciling the information collected from them. In JAD, key users met with management representatives and systems developers, sometimes for a day, sometimes for an entire week, to determine requirements for a system. The process was very structured, typically led by a trained JAD facilitator whose primary role it was to keep the process moving. JAD essentially allowed for many interviews to be conducted at once and for contradictions to be reconciled on the spot (although not always possible). A JAD session was typically held off-site to minimize the distractions participants would experience if working at the office. There has

been little empirical research into the effectiveness of JAD. One study reported that JAD was superior to traditional methods, with respect to the quality of user–designer interactions, effectiveness of consensus management, and user acceptance of design specifications (Purvis and Sambamurthy, 1997). Other studies combined JAD with other approaches for managing group work, from electronic group support to the nominal group technique. JADs run with electronic group support had more equal participation among group members but lacked the session discipline and conflict resolution common to traditional JAD (Carmel et al., 1995). JAD combined with the nominal group technique was found to be more effective than traditional JAD, although just as efficient, with higher levels of user satisfaction and better system requirements determination (Duggan and Thachenkary, 2004).

28.3.3 Other Structured Approaches

Information engineering (IE) is a structured approach to systems analysis and design originally developed by Clive Finkelstein (http://www.ies.aust.com/cbfindex.htm). He later worked with James Martin, who developed his own version of the methodology in the mid-1980s (Martin, 1986). As with many other structured approaches to systems analysis and design, IE depended on sets of related and interconnected diagramming models. These models included entity–relationship diagrams, data flow diagrams, decision trees (called action diagrams), and report and screen layout tools. IE also stressed the importance to the development process of automated tools, which allowed high levels of user participation, as well as high levels of horizontal integration (between systems) and of vertical integration (linking systems to top management goals and corporate strategy). IE had four stages: (1) information strategy planning; (2) business area analysis; (3) system design; and (4) construction. The planning phase focused on the entire enterprise, while a different business area analysis would be done for each different business area. These two processes together took from 9 to 18 months to complete. The latter stage focused on identifying the processes and data needed for each business area. Design was conducted via automated development tools, and construction was aided by code generators and other tools. At all stages of the IE process, knowledge was stored in an encyclopedia, or central repository.

Martin later worked with Texas Instruments on instantiating the methodology into a CASE tool called IEF, for information engineering facility. IEF was released in 1987. In 1997, Texas Instruments sold IEF to Sterling Software, which was later acquired by Computer Associates.

RAD was a development methodology also credited to James Martin (1991). The idea behind RAD was captured in its name: dramatically shorten the time necessary for systems to be developed. Complex business systems typically took years to develop using structured analysis and design processes, but with the dynamic pace of business in an expanding global economy, firms could not wait for systems that, once completed, might no longer be adequate models of their business processes they modeled. According to Martin, a system that would take 2 years to complete following the traditional approach might instead be completed in 6 months following the RAD approach.

RAD was purported to save time and other related resources, like money, because of how it was designed to work. First RAD made heavy use of JAD and of CASE tools to support prototyping. The first JAD meetings in a RAD effort might involve prototyping very early in the process, before a more traditional JAD would. The prototype developed also tended to become the basis for the production system, rather than being thrown away, as discussed previously. Second, the prototyping process in a RAD required more intensive participation from users in a true partnership with developers. Users might also have become involved in the design process itself instead of ending their participation after requirements determination was complete, which was more typically the case using traditional approaches. Martin (1991) also argued that developers had to be trained in the right skills and methodologies, and management had to lend its complete support, for RAD to be successful.

As good as it might sound, RAD was not without its problems. Sometimes, due to the speed with which systems were developed, some of the basics of traditional systems development were overlooked. These included interface consistency across the system, programming standards such as documentation

and data naming standards, upward scalability to serve larger numbers of more diverse users, and planning for system administration chores such as database maintenance and organization, backup and recovery, and so on (Bourne, 1994).

28.3.4 Alternative Development Approaches and Practices

Even though it was not universally adopted, the structured approach to systems development dominated development work for many years. Before the transition to agile methods that occurred in the late 1990s and the early part of the twenty-first century, there existed several alternatives to the structured approach. One, the RUP, was created to guide object-oriented systems development efforts. Another, participatory design, focused more on people and creative hands-on techniques for development rather than focusing on the technology and using it to support development. A third approach, reuse, is really not so much a separate methodology as it is a practice created to make any development process more efficient through reusing existing software code and components. Each of these approaches and practices are discussed in more detail in the sections that follow.

RUP was a development methodology that emerged from the object-oriented perspective on analysis and design. It had its origins in the work of Jacobson et al. (1999), although the process now is owned by IBM (http://www-01.ibm.com/software/awdtools/rup/). The approach was built around iteration, with a focus on being risk-driven (Aked, 2003; Ambler, 2005). The risk-driven approach refers to the practice of tackling head on concerns that could adversely affect the development project, rather than dealing with easy issues first and dealing with risk later (Aked, 2003). The methodology crossed four phases (inception, elaboration, construction, and transition) with nine disciplines, which described the different types of work to be done. These nine disciplines are: (1) business modeling; (2) requirements; (3) analysis and design; (4) implementation; (5) test; (6) deployment; (7) configuration and change management; (8) project management; and (9) environment. The phases and disciplines are often shown in what is called a "hump diagram," where the relative effort devoted to each discipline within each phase is shown (Figure 28.4 shows only the first six disciplines). Each phase was also divided into a number of iterations. At the end of each phase, there was a go/no go decision, much as was the case in an SDLC from the structured approach.

The inception phase included defining scope, determining the feasibility of the project, understanding user requirements, and preparing a software development plan. In the elaboration phase, detailed

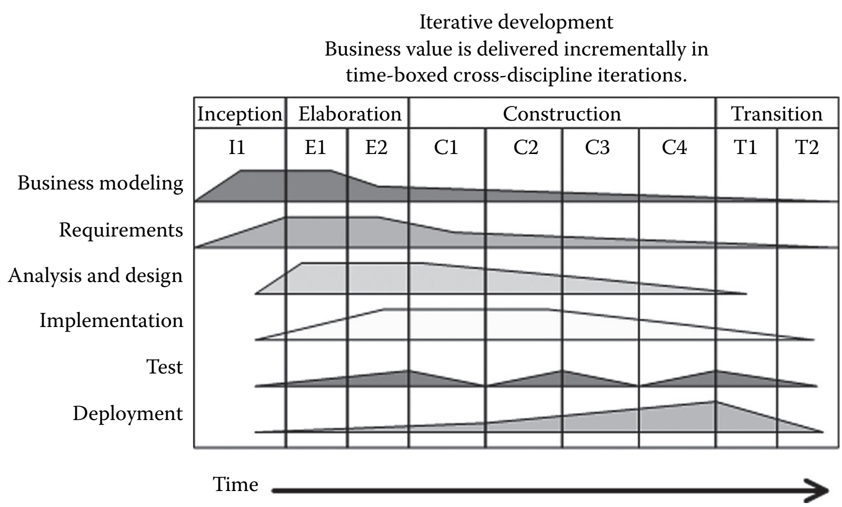

FIGURE 28.4 The rational unified process depicted in a hump diagram. (This figure is in the public domain and is used by permission of its author Dutchguilder. http://en.wikipedia.org/wiki/File:Development-iterative.gif)

user requirements and a baseline systems architecture were developed. Analysis and design activities constituted the bulk of the elaboration phase. In the construction phase, the software was coded, tested, and documented. In the transition phase, the system was deployed and the users were trained and supported. The construction phase was generally the longest and the most resource intensive. The elaboration phase was also long but less resource intensive, relatively speaking. The transition phase was resource intensive but short. The inception phase was short and the least resource intensive.

The nine disciplines were one way to package the skills and processes needed for successful systems development. The first six, from business modeling to deployment, corresponded to a typical development process, from planning through analysis, design, testing, and implementation. Configuration and change management corresponded to the ongoing maintenance process, which follows implementation. Both project management and environment ran more or less throughout the development process. While the former is self-explanatory, the latter refers to making sure the appropriate guidance and tools are available to the development (and maintenance) team throughout the process (Ambler, 2005). As RUP came out of the object-oriented perspective, for implementation it relied heavily on the unified modeling language (UML) (Booch et al., 2005). RUP and UML were captured in the Rational Rose CASE tool, which is now sold by IBM as the Rational series of tools. Stories of RUP use in organizations and the resulting successes and problems were typically told in case study form (see Hanssen et al., 2005, and Lee, 2006, for examples).

Participatory design was a very different approach to systems development than anything presented so far. Developed in Northern Europe, participatory design focused primarily on the system's users and how the system would affect their work lives. In some cases, the entire user community might play an active role in the systems development process, while in others, users might select representatives to represent them. Typically, system developers worked for the users. Management and outside consultants provided advice but did not control the process. Participatory design efforts included a repertoire of flexible practices and general guidelines. Running through the repertoire were the twin themes of mutual reciprocal learning, in which users and developers teach each other about work and technology, respectively, and design by doing, which resembles prototyping but does not necessarily require sophisticated computing to implement (Carmel et al., 1993). While well known in Northern Europe, especially in the Nordic countries, participatory design was rarely followed elsewhere.

Reuse was the use of previously written software resources in new applications. As so many bits and pieces of applications are relatively generic across applications, it seems intuitive that great savings could be achieved in many areas if those generic bits and pieces did not have to be written anew each time they were needed. Reuse should increase programmer productivity, as being able to use existing software for some functions meant they could perform more work in the same amount of time. Reuse should also decrease development time, minimizing schedule overruns. Because existing pieces of software have already been tested, reusing them should also result in higher quality software with lower defect rates, which is easier to maintain.

Although reuse could conceivably apply to many different aspects of systems, typically it was most commonly applied to object-oriented code and components. In object-oriented code, both data and function are combined in one item. For example, an employee object would contain both the data about employees and the instructions necessary for calculating payroll for a variety of job types. The object could be used in any application that dealt with employees, but if changes had to be made in calculating payroll for different type employees, the changes would only have to be made to the object and not to the various applications that used it. By definition, using the employee object in more than one application constitutes reuse. As with CASE tools and structured development, developers were slow to adopt object-orientation (Fichman and Kemerer, 1993), although that has changed dramatically in the past few years. Today, four of the five most used programming languages are object-oriented (Java, C#, C++, and Objective-C, with the other being C) (TIOBE, 2012). Components are general-purpose pieces of software that can be used interchangeably in many different programs. Components can be as small as objects or as large as pieces of software that handle single business functions, such as currency conversion. The idea behind component-based development is the assembly of an application

from many different components at many different levels of complexity and size. Reuse of objects and components has proven to be effective, resulting in increased productivity, reduced defect density, and reduced rework (Basili et al., 1996). Reuse has it problems, however. In a study of 24 European companies that undertook reuse projects, one-third of the projects failed (Maurizio et al., 2002). The reasons for failure were not technical—they were managerial. How changes to work processes that govern reuse are implemented and managed are key to its success (Sherif et al., 2006).

28.4 Agile Development

Although the engineering approach remains in use today, to many critics, it has become bloated and slow, no longer as useful in a global economy that runs on Internet time. The convergence of the object-oriented approach and the Internet economy set the stage for the current major phase in systems development. Relying on object-orientation and the need for speed, the new approach sacrifices the milestones and multiple phases of the engineering approach in favor of close cooperation between developers and clients, combining many life cycle phases into few phases, and multiple rapid releases of software. Although there are many individual methods that reflect the new approach, collectively they are called the agile methodologies.

Many different individual methodologies come under the umbrella of agile methodologies. In February 2001, many of the proponents of these alternative approaches to systems analysis and design met in Utah, USA, to reach a consensus on many of the underlying principles their various approaches contained. This meeting let to a document they called "The Agile Manifesto" (Beck et al., 2001). The agile methodologies share 12 principles (http://www.agilemanifesto.org/principles.html), which can be summarized in three key points: (1) a focus on adaptive rather than predictive methodologies, (2) a focus on people rather than roles, and (3) a focus on self-adaptive processes (Valacich et al., 2012). Agile adherents argue that software development methodologies adapted from engineering generally are not a good fit for the reality of developing software. In the engineering disciplines, such as civil engineering, requirements tend to be well understood. Once the creative and difficult work of design is completed, construction becomes very predictable (Fowler, 2005). In addition, construction may account for as much as 90% of the total project effort. For software, on the other hand, requirements are rarely understood well, and they change continually during the lifetime of the project. Construction may account for as little as 15% of the total project effort, leaving design to constitute as much as 50% of the project effort (McConnell, 1996), depending on the project type. Applying techniques that work well for predictable, stable projects, like building a bridge, tend not to work well for fluid, design-heavy projects like writing software, say the agile methodology proponents. One mechanism for dealing with a lack of predictability, which all agile methodologies share, is iterative development. Iterative development focuses on the frequent production of working versions of a system that have a subset of the total number of required features. Iterative development provides feedback to customers and developers alike.

Second, the focus on people in agile methodologies is a focus on individuals rather than on the roles that people perform. The roles that people fill, of systems analyst or tester or manager, are not as important as the individuals who fill those roles. Fowler (2005) argues that the focus on engineering principles applied to systems development has resulted in a view of people as interchangeable units instead of a view of people as talented individuals, each of which has something unique to bring to the development team. Third, the agile methodologies also promote a self-adaptive software development process. As software is developed, the process used to develop it should be refined and improved. Development teams can do this through a review process, often associated with the completion of iterations.

28.4.1 eXtreme Programming

One of the best known and most written about agile methodologies is called eXtreme programming. Developed by Kent Beck in the late 1990s (Beck, 2000), eXtreme programming illustrates many of the central philosophies of this new approach to systems development. eXtreme programming is

distinguished by its short development cycles, its incremental planning approach, its focus on automated tests written by programmers and customers to monitor the process of development, and its reliance on an evolutionary approach to development that lasts throughout the lifetime of the system. One of the key emphases of eXtreme programming is having a customer on-site during the development process. Another is its use of two-person programming teams.

Under this approach, users generate stories that serve as the basis for system functions and features. These user requirements are not consolidated into a single, detailed and complete design specification, as would be expected in an engineering-based development effort. Instead, requirements serve as the basis for a design, which is captured in code and then tested. Coding and testing are intimately related parts of the same process. The programmers who write the code also write the tests. The emphasis is on testing those things that can break or go wrong, not on testing everything. The overall philosophy behind eXtreme programming is that code will be integrated into the system it is being developed for and tested within a few hours after it has been written. If all the tests run successfully, then development proceeds. If not, the code is reworked until the tests are successful. Pair programming makes the code-and-test process work smoothly. All coding and testing is done by two people working together, writing code and writing tests. The programmers work together on the problem they are trying to solve, exchanging information and insight and sharing skills.

To continually improve the quality of the design, eXtreme programming relies on a practice called simple design. Simple design is what it sounds like: keeping the design simple. According to Beck (2000), it is common for developers and programmers to look ahead and to try to anticipate changes in how the system will work and to design accordingly. Many times, those anticipated future conditions never materialize, and the time and effort that went into designing for the uncertain future is wasted. Under the eXtreme programming approach, design should focus on solving the immediate problem, not on solving future problems that may or may not occur.

28.4.2 Scrum

Scrum originated in 1995 and was developed by Jeff Sutherland and Ken Schwaber (Schwaber and Sutherland, 2011). Scrum represents a framework that includes Scrum teams and their associated roles, events, artifacts, and rules. Each team consists of three roles: the product owner, the development team, and the Scrum master. The owner is essentially accountable for the product and the work that produces it. The development team is small, within the preferred range of 3–9. The Scrum master is there to teach and enforce the rules (which vary by team and by product). Scrum is designed for speed and for multiple functional product releases. The primary unit is the sprint, a 1 month (or less) unit of effort. Each sprint is a complete project in and of itself. It starts with an 8 hour sprint planning meeting, which focuses on two questions: What will need to be delivered by the end of the sprint and how will the work needed to do that be accomplished? The sprint goal provides guidance for the team for the duration of the sprint. During the sprint, there is a daily Scrum, a 15 min meeting held to essentially evaluate what progress has been made within the past 24 hours and what still needs to be done. At the end of the sprint, there are two other meetings, the sprint review (4 hours) and the sprint retrospective (3 hours). While the review focuses on the product, what has been accomplished, and what needs to be done in the next sprint, the retrospective is more broad. It focuses as well on the performance of the team and how it can improve in the next sprint. There are three primary artifacts in the Scrum process. The first is the product backlog. This is an ordered list of everything that might be included in the product, that is, a list of potential requirements. The list includes "all features, functions, requirements, enhancements and fixes (Schwaber and Sutherland, 2011, p. 12)" that make up all the changes to be made to the product. The sprint backlog is a subset of the product backlog, consisting of only those items to be addressed in a particular sprint. Finally, the increment is the sum of all the product backlog items completed during a sprint. Each increment must be in complete enough form to be useable, whether or not the product owner decides to release it. It is called an increment because it represents an increment

of total functionality for the product. Each increment is thoroughly tested, not only as a standalone but also in conjunction with all prior increments.

28.4.3 Agile Performance

Several studies have investigated agile methods in practice. One study, a survey of over 100 agile projects, found three primary critical success factors for agile development (Chow and Cao, 2008). The first is delivery strategy, which refers to the continuous delivery of working software in short time scales. The second is following agile software engineering practices. That means managers and programmers must continually focus on technical excellence and simple design. The third critical success factor is team capability, which refers to the agile principle of building projects around motivated individuals.

Another study found that, once implemented, agile methods can lead to improved job satisfaction and productivity on the part of programmers (Dyba and Dingsoyr, 2008). They can also lead to increased customer satisfaction, even though the role of on-site customer representative can be tiring and so not sustainable for very long. Agile methods tend to work best in small projects. In some instances, it may make sense to combine them with traditional development methods.

A detailed study of one agile development effort showed that some of the key principles of agile development had to be modified to help ensure success (Fruhling and DeVreede, 2006). For example, in the agile project studied, pair programming was not always used, especially when resources were needed elsewhere. Second, the process of writing the test case first and then the code was followed until the system became too complex. Third, the customer was not located in the same place as the programmers. Instead, the customer stayed in contact through regular meetings and continual e-mail and phone communication. Even with these modifications, the resulting system was considered a success—fewer than 10 updates were issued due to errors and none were issued due to implementing the wrong functionalities. Working together, the users and developers were able to clarify system requirements and create a user interface that was easy to learn and use.

28.5 Reconciliation and the Next Phase

Although the agile approach to systems development has many adherents who believe it is the only viable approach, others have found that agile works best for certain types of development projects. Traditional, or plan-based, approaches work best for a different set of development projects. For example, Boehm and Turner (2004) argue that agile methods are better for projects that involve small teams and small products; that agile methods are untested on safety-critical products; that the approach works best in a dynamic as opposed to stable environment; that agile projects require a critical mass of scarce agility experts; and that the approach works best where the participants do well in a work environment that is openly defined and even chaotic. Traditional approaches, then, work best for large, complex, and critical products where the product environment is stable and relatively few experts are needed during the course of development and where people are most comfortable in a work environment where their roles are well-defined and practices and procedures are clear. Additionally, agile methods are thought to work best where participants are collocated, while plan-based methods can function just as well where participants are physically distributed. Meanwhile, there is some evidence that agile methods may be used successfully in environments and for products that do not fit the constraints outlined earlier (Abrahamsson et al., 2009). Similarly, some of the practices thought central to agility, such as having an on-site customer and pair programming, may not contribute to agility as much as previously thought (Conboy, 2009).

In fact, there seems to be a movement toward using mixed approaches for systems development, where some aspects of plan-based and agile approaches are used together. Port and Bui (2009) showed through simulation that hybrid approaches yielded better results than either traditional or agile approaches alone. Results were measured by the value and the cost of the requirements implemented during the

simulation from both pure and hybrid approaches. In 2008, Baskerville et al. studied three software development companies where parts of the development process were supported through Scrum, while other parts were carried out using traditional plan-based methods, including a heavy emphasis on project management techniques (Baskerville et al., 2009). The people they interviewed stressed the need for alignment between the two approaches, where alignment was “described as necessary to ensure that the work carried out by the Scrum teams [wa]s in line with the overall scope document, budget, and project plan (Baskerville et al., 2009, p. 551).” The Scrum process and teams existed within a larger wrapper consisting of the traditional project management structure. Baskerville et al. (2009) speculated that the next stage in the overall march of systems development processes, which they called “post-agility,” will blend the goals of agility and the plan-based approach through new ways of organizing, managing and communicating, and through new methods and software tools. Agility would no longer be a separate approach but would be deeply incorporated into all systems development methodologies. As they pointed out, the post-agility era would also be the post-plan-driven era.

28.6 Future Research Opportunities

The study of information systems development—of the methodologies, methods, and tools that have been created over the years to facilitate and support the process—was once the primary topic of research in the information systems field (Sidorova et al., 2008). Today, the topic is less studied, but it remains an important part of the field. There are still several interesting questions related to systems development that need to be investigated. This chapter suggests at least three such areas: (1) comparisons of different approaches to systems development, (2) investigations into the practices and processes currently used in industry, and (3) speculative studies of what will constitute the next stage in the evolution of system development approaches.

In the Management Information Systems (MIS) field, there has been a long tradition of studies that compare two or more approaches to systems development (see, for example, Howard et al., 1999). These studies have typically been experimental in nature, where different groups or individuals have used competing methods or tools to address a specific systems development problem. While many of these studies have compared different aspects of the structured plan-driven approach, relatively few have compared the structured approach to the object-oriented approach. Fewer still have compared plan-driven and agile approaches. This is the case even though agile methods have existed for over a decade, as of this writing. There is a clear need for systematic experimental studies that compare different approaches to systems development to each other. For both research and practical reasons, we should strive to understand the relative strengths and weaknesses of the various approaches.

A second area of research that has great potential is the study of how organizations actually approach systems development. While agile methods have received much attention in the trade press, to what extent have organizations actually adopted them? We know from past research that industry is slow to adopt new approaches to development (Fichman and Kemerer, 1993). Is that also the case for agile methods today? To what extent do organizations adopt agile methods for some projects but plan-driven approaches for others? And on what basis do they choose which approach to use? With the widespread practice of organizations outsourcing many aspects of their systems development, how do they reconcile the need for planning apparent in outsourcing with the need for agility? Also, to what extent do companies use RUP and/or follow reuse policies? These are just some of the many questions that can be answered only through field work in organizations that develop systems, either for sale or for their own use. Industry-based research will help identify best practices that can benefit many different organizations as they seek to improve their systems development efforts.

Finally, as Baskerville et al. (2009) suggested, we are on the verge of a new, fourth approach to systems development. What will this post-agility, post-plan-driven era look like? What should it look like? How can its advent be hastened? We are in a unique position vis-a-vis those who studied the transitions between the previous approaches to systems development—few of them anticipated the

previous transitions. Study of the transitions, and the new approaches they produced, came only after they had already occurred. Meanwhile, we know the next transition is coming, and we have some idea of what the next approach will look like. Not only can we anticipate the change and study it as it occurs, but we can also influence the form it eventually takes and its underlying philosophy.

28.7 Conclusions

Administrative information systems have been a part of organizational life for almost 60 years. During that time, information systems technology, organizations, the business environment, and the global economy have all changed dramatically. Information systems development methods have evolved to better deal with and take advantage of changes in technology as well as in the various external environments that affect it. Initially, when the technology was relatively primitive, systems development followed a craft approach. This was suitable for an era without standards, where computers varied considerably by vendor and by model, and where there were no standard programming languages, much less standard development approaches. Although the systems developed during this era worked, and some were truly innovative and worked amazingly well, the lack of predictability and documentation and the costs involved became too much to bear. Toward the end of this phase, standardized development methodologies were developed, just as standardized procedural programming languages had been developed. With standardization came control: over budgets, over schedules, over functionality, and over information systems personnel. Planning became paramount, and artists became engineers. While there was some resistance to this transformation, the plan-based approach soon became the norm. But in a dynamic human enterprise such as systems development, things did not stay the same for long. The plan-based approach had its own problems. To its critics, it was too slow to keep up with a dynamic business environment, it was too bloated, and it was too big. Such critiques were becoming common even before the Internet and the concept of "Internet time" exploded on the scene. Eventually, a new approach, agility, emerged. It was slow to spread, but eventually agility became just as popular as the plan-based approach. Today, these two approaches coexist, and there is some evidence to suggest that aspects of the two perspectives are slowly merging into a new approach. We can call this the "post-agility" phase, although a new and more descriptive name will be invented as the approach itself becomes better articulated. We know from the history of systems development approaches that the next phase will take some time yet to fully emerge. It may be 5 years from now, or it may be 10. If there is a revision of this chapter 10 years from now, the new phase will almost certainly be included. While there is still much uncertainty about the next phase, what it will encompass, and what it will be called, what is certain is that there will eventually be a fourth phase and that it will not be the last.

Human-Centered System Development

Jennifer Tucker
U.S. Department of Agriculture

29.1 Introduction

In the previous edition of this handbook, this chapter opened with the declaration, "The last decade has seen a significant change in the information technology landscape, resulting in a fundamental shift in the activities and skills required of technology professionals and teams." Those words were typed at about the same time that Facebook was being coded in a Harvard dorm room, 3 years before the first iPhone app launched, and 4 years before the Android source code was released. In only a few years, the landscape of information technology (IT) and systems development has again fundamentally changed.

With the evolution of computer languages, target platforms, and development methods, the skills demanded of IT professionals also evolve. In addition to maintaining and expanding technical skills, most IT professionals must communicate with an increasing technologically literate user base, navigate faster development cycles, and work in complex interdisciplinary teams. There is, of course, still the mystical archetype of the lone programmer huddled in the basement coding through the night with pizza boxes piled high. Today's zeitgeist, however, also recognizes that this same programmer might become the next tech company's Chief Executive Officer; and the project that begins as a loner's experiment might become a venture capitalist's target.

The success stories of today's social web, where every programmer is a potential millionaire, paint a positive view of the state of systems and software development. Statistics across the industry, however, raise more concern. While some question the study methods and criteria, the often-quoted Standish CHAOS reports signal ongoing industry dysfunction. The CHAOS 2000 report found that 23% of the projects studied essentially failed (Standish Group, 2001). The CHAOS Summary 2009 (Standish Group, 2010) concluded that just 32% of all projects were delivered on time, on budget, with required features and functions; that 44% of projects were "challenged" (e.g., they were considered late, over budget, and/or with less than the required features and functions); and that 24% failed (e.g., were canceled or just never used) (Standish Group, 2009).

These and other studies highlight different failure rates for different project types, but importantly also highlight the common factors contributing to these failures. These reasons often include lack of user involvement, poor project planning and execution, lack of executive support, stakeholder politics, an

overemphasis on process activities, and poor communication or lack of shared understanding between business and technology groups (Standish Group, 2001, 2010; Schneider, 2002; Charette, 2005; Dyba, 2005; Kelly, 2007; Krigsman, 2009; McCafferty, 2010). Even with our best development methodologies and technological sophistication, the human dimension of systems and software development remains the key element to success.

At the most basic level, the output from any development project emerges from the conversations and collaboration among individuals working together over time. As such, success can be influenced by the ability to manage the following types of human dynamics:

- *Individual development*: Today's technology professional must be a lifelong learner of different application development frameworks, platforms, programming and markup languages, and development tools. Individuals, therefore, must have self-awareness about personal learning style and make strategic choices about whether and where to specialize and generalize. Like all professionals, technologists should also have a sense of their strengths, weaknesses, and preferences in how they work with others. Do they prefer working in a structured, predictable environment, or do they like flexibility and change? Do they prefer to work alone or with others? Too often, technology professionals are drawn to the technology aspects of the work, without fully considering the people-oriented dimension of the career choices being made. Furthermore, technical mentors may not always help their technical protégées navigate these more personal questions of self-development.
- *Team collaboration*: The range of talents required of an IT development team today is both broad and deep. Today's development teams include functional experts, business analysts, architects, programmers, content strategists and writers, data modelers and scientists, network and systems administrators, and project managers. In one study of IT-focused organizations, only 12% of IT professionals surveyed reported their role as being programmer or developer (Tucker et al., 2004). The result is that IT teams, which once shared a common technical base for building relationships, are coming together from separate specialties and backgrounds within their own fields. This diversity creates profound opportunities for collaboration if team members are able to transfer knowledge internally and communicate effectively, but it can also lead to miscommunication and misfires if not managed well.
- *User communication*: Technical individuals and teams rarely work in a vacuum. Even in teams where a project manager or business analyst serves as a primary point person for customers, developers need to interpret requirements and understand how their work will meet the user's or customer's needs. Self-perception, self-expression, interpersonal skills, decision making, and stress management are all factors of emotional intelligence (EQ) that shape the ability to work effectively with customers (Stein and Book, 2006), and motivational states and cognitive preferences can dramatically shape understanding and interpretation. Deciding how users are to be treated and engaged in a systems development process, and then following through even when conflict is encountered, is a critical factor in the design of a technology program.

These realities and dimensions of the systems development experience call us to again reexamine IT and systems development work from a human dynamics perspective. This chapter considers the underlying principles informing human-centered systems development and considers applications and directions for future research.

29.2 Principles and Applications

Understanding human-centered systems development begins with defining the term itself. For the purpose of this chapter, human-centered systems development considers the people side of systems development: the personality dynamics of IT professionals, the people-related dynamics of IT teams, and the interpersonal elements of the systems development life cycle.

29.2.1 Personality Dynamics of IT Professionals

Many research studies have used psychometric tools to describe the personality dynamics of IT professionals. While these studies have ranged in design, they collectively reveal that certain personality characteristics tend to be more and less prevalent among IT specialists than the general population (Mastor and Ismael, 2004; Tucker et al., 2004; Williamson et al., 2005; Lounsbury et al., 2007). These distinctive characteristics include

- A higher preference for logical, impersonal, and objective analysis, sometimes captured as tough-mindedness
- Higher levels of intrinsic motivation, personal control, and emotional resilience
- Higher levels of independence
- High desire for supervisor support, but without the desire for increased levels of control by those same supervisors (consistent with independence)
- Lower levels of rules orientation and conformity, which in some psychological tests are characterized as conscientiousness
- Lower levels of political savvy and interest, sometimes known as image management
- Lower needs for interpersonal connection and inclusion in other people's social activities

The practical impact of this research is that understanding these personality characteristics both reveals the common strengths that information technologists might bring to their work and points to possible systemic weaknesses or blind spots that may occur when strengths are overdone. The strengths of logic, objectivity, independence, and control can yield powerful technology solutions, but they also make it understandable why the mythos of the lone, independent, even awkward coder is so persistent and so often encountered in real life.

When overdone, the strengths most commonly associated with IT professionals can be perceived as a lack of empathy for the user, a lack of concern for relationship management aspects of the development process, or a bias toward working on interesting individual tasks rather than attending to more routine team needs.

Independence and personal control over work are often repeated themes when referencing technology professional preferences. Developing high-quality software requires attention to detail and clear controls. Controlling quality, however, is different from controlling the people developing the code, particularly when those people value high levels of independence and personal autonomy. Structured project management addresses software quality because it introduces controls and testing check points that prevent low quality code from being committed and released. Too much management, however, can stifle innovation and creativity among the people creating that code. An awareness of these human dynamics is vital for leaders seeking ways to control the code without overly controlling the coders.

Interpersonal and relationship management skills are vital in any systems development effort, but while increasingly referenced in curriculum models, are not central in the formal education of most technology professionals. Once in the workplace, many technology professionals tend to avoid training that focuses on the development of interpersonal and communication skills, believing that such investment of time and resources is not as beneficial as learning a new technical skill.

At the same time, personal experience suggests that many technical specialists have at least occasionally experienced conflict with team members, misunderstandings with the boss, or confusion with end users or clients. Many of these interpersonal issues can be traced to fundamental style or communication differences rather than a technical deficiency. Technical professionals who recognize these root causes are better prepared to manage problems effectively, leading to better technical work. Understanding what one brings to the team from a human dynamics standpoint, and how that might mesh or clash with coworkers, is a key starting point.

29.2.2 IT Team Dynamics

The increasing specialization of roles in systems development brings together teams of engineers, business analysts, architects, developers, content strategists, testers, and project managers to guide technology projects to fruition. Larger team sizes lead to more complexity, and while many acknowledge that project success is often linked to the "people side" of the equation, there are no agreed upon algorithms for project success. Project success in the real world, in fact, comes from carefully balancing a variety of factors. Just as overdone personality strengths become weaknesses, an overemphasis on any particular project or team factor becomes a liability as well.

Human-centered systems development requires understanding factors and models from a variety of fields, including psychology, process improvement, project management, and organization development. This section reviews a number of factors important to the success of technology teams (Ahern et al., 2001; Rutledge and Tucker, 2006; Basri and O'Connor, 2011).

29.2.2.1 Mission and Goal Clarity

A shared understanding of the goal of any particular project keeps both the project team and user base focused on the end state and provides a stable benchmark when tough trade-offs and decisions must be made. When different segments of a project team hold different understandings of the mission, disconnects and conflicts may occur without people actually realizing their cause.

For example, drawing from a true case study, picture a large-scale software radio development program with teams distributed across a number of sites. While the program had an overarching and rather lengthy mission statement, people generally reported either not knowing what it was, or, not really understanding what it meant. To explore this, two teams in the program were asked to develop a statement summarizing the overarching mission of the project. One team responded that the goal was to create a low-cost piece of integrated software and hardware that would require little maintenance once fielded. The second team responded that the goal was to develop cutting-edge technology that would advance the software radio field and spark new technology investments. There had been a variety of conflicts between these two teams, and integration between systems had consistently encountered difficulties and delays. Unfortunately, the teams had not ever discovered their fundamental disconnect, leading to conflicts that were ultimately based on foundationally different ideas of the project mission.

Any factor that is overemphasized can, of course, lead to blind spots. A shared understanding of a mission provides teams with a target against which to mutually align and a common goal around which to rally. When there is too much emphasis on mission achievement, however, the team can miss shifts in the environment that led to the initial need, leading to possible obsolescence in the mission itself. Additionally, an overemphasis on goal orientation can lead to high levels of team stress if too much pressure is imposed.

29.2.2.2 Structure and Leadership

Structure and leadership includes such formal elements as role clarity, reporting relationships, and organizational structure, and informal elements such as power dynamics, personal accountability, and empowerment. Structure provides information about hierarchies, governance, and team organization. Leadership can be either formal as managers give direction, make decisions, and allocate resources; or informal and emergent as different team members lead each other as the project unfolds (Howell et al., 1986; Carter, 2004; Rutledge and Tucker, 2006; Senge, 2006).

Structure and leadership often evolve as organizations and teams grow. The team that begins as two programmers grows into a small team and beyond. Technical questions become supplemented by organizational questions of centralization versus decentralization, and self-directed teams versus matrix relationships. These are important questions about how the team functions and also reveal dynamics about how a technology team engages with others outside the group.

For example, in formal organizations, examining an organization chart (if there is one), can reveal the team's relationship with its users. Who is the person or group responsible for ensuring that the users' voices are heard? Where does this role reside on the chart, and how much power is inherent in the position?

The same teams described earlier that struggled with mission clarity also struggled with user relationships and senior stakeholder buy-in. The team responsible for customer relationships was organizationally located in an entirely different team than the engineering and testing teams, and there were few formal or even informal connections between them. As such, the team responsible for relationship management was listening to the user base, but the structure of the large program did not facilitate information flow from one part of the program to another. One key consequence of this was that the customer felt heard, but when elements of the product were delivered, there were significant usability gaps between what the customer had asked for and what was delivered.

Over time, informal connections between project team members built informal pathways for questions and feedback, but leaders did not make easy transmission of customer feedback a priority, causing inefficiency in communication and a great deal of invisible labor behind the scenes. The informal leadership of team members ultimately evolved into an unwritten "shadow org chart" for information sharing. The degree of match between formal and informal power structures on a team reveals a great deal about the efficiency and effectiveness of team operations, and the degree to which formal leadership is respected and followed.

A very different case study can be seen in the structure and leadership of the open source community that develops the operating system Linux. This is a model where structure and leadership are highly interdependent. The Linux organizational structure is centered on a person rather than a role; Linus Torvalds, the "benevolent dictator of Planet Linux," (Rivlin, 2003) and a small set of key deputies hold decision-making authority for all elements of a Linux release. Outside this structure, there are loose networks of developers and contributors but no formal organization charts, reporting relationships, or hierarchies.

In this model, a small core of formal leadership is at the center, making the institutional decisions that define the product. In the absence of formal institutional structures, technical and people leadership from Torvalds is cited as a defining factor in the success of the overall enterprise (Rivlin, 2003; Vaughan-Nichols, 2010). Complementing this, informal and emergent leadership is exercised as individual developers choose what features to work on and who to follow; it is this grassroots leadership that ultimately provides the assets from which the formal leadership core can select. While Torvalds may be the central figure, the relationships across this community form an informal network that provides intellectual capital and becomes its own type of organizational structure.

29.2.2.3 Process and Communication

How much team processes are known, agreed on, communicated, and acted upon greatly impacts team effectiveness and morale. While structure defines roles and relationships, process defines how work flows between these roles to lead to decisions and deliverables. Software development models, business processes, workflow, and decision matrices all fall under the category of process. While process and communication are often treated separately in process management, they are fundamentally linked; communication between team members, whether technically or interpersonally mediated, is generally the mechanism by which process is expressed.

In the past, the technology industry attacked the dynamic problems of system development with an increased focus on process, creating a plethora of standards, protocols, and maturity models. As noted previously, however, any strength maximized can become a liability; and process management taken too far can result in an overemphasis on project reporting and process documentation, compromising functional delivery.

This is an area where the pendulum may be swinging, or at least diversifying. In the previous edition of this handbook, this chapter declared, "Every complex endeavor needs an organized plan to keep it

on track." Since that edition, however, the success of emergent start-ups and open source projects has called this project management assumption into question. For example, Facebook proudly proclaims its preference for "The Hacker Way" through the mantra: "Done is better than perfect." Facebook has embraced a development process centered upon small iterative releases, with constant testing both to correct errors and to identify the next steps (Zuckerberg, 2012). Free and open source software development also usually does not follow formal process models or plan-driven approaches because it is generally based on volunteer collaboration; yet, these projects can generate high-quality products quite quickly (Magdalenoa et al., 2012).

These development processes are very different from the structured waterfall methods of the past and require different communication approaches and styles. The absence of plan-driven process does not, of course, mean the absence of process. The question is: How do the formal and informal processes and communication pathways within a team support or detract from the team's success, however that is measured, and how do the processes encourage or discourage the participation of the technical professionals most qualified to do the work? An emphasis on structured, plan-driven process and communication appeals to many professionals. It is predictable, clear, and when managed effectively, efficient. Other professionals are more attracted to the "Hacker Way," where the product emerges from the unpredictability of trying out new ideas. It is innovative, flexible, and when managed effectively, efficient.

Different process approaches have different impacts that can be both positive and negative. These impacts may also be perceived differently by people with different personalities. What is a positive process practice or communication approach for one person may be problematic for another. Just as engineers must understand the impact of different architecture and design choices, those working in a human-centered systems development context must anticipate how different process and communication approaches are likely to impact different people and plan accordingly. This may mean recruiting people that either enhance or counter-balance different team characteristics, customizing communication for different people based on individual values and styles, and identifying and monitoring the risks that may emerge when specific approaches are too far over-emphasized.

29.2.2.4 Interpersonal Skills

The unequaled mourning over the death of Steve Jobs sent tremors of paradox through the leadership development community. After years of advocating the importance of interpersonal skills in leading organizations and teams, many struggled with the sense of cognitive dissonance that a man so feared would also be so celebrated for his ability to inspire other people. How could this leader, known for his angry outbursts and harsh feedback, be so revered?

A review of leadership articles and blogs published shortly after Jobs' death reveals a common theme: Jobs' leadership style worked because of his unique blend of technical and design intelligence, because of his insistence on excellence from everyone around him, and because he was inspirational in how he communicated his vision to others (Isaacson, 2012). Many articles, however, also carried a warning echoed by leadership coaches far and wide: "Don't try this at home" (Allen, 2011; Nocera, 2011; Riggio, 2012). Jobs' ability to lead despite his difficult interpersonal style was cited as many as an anomaly; something "mere mortals" should not attempt.

From a practical viewpoint, it is more useful, perhaps, to reframe the situation as a matter of fit. Jobs had a specific style that attracted certain people to him, but there are likely many that self-selected away from him as a result of that same style. Investing in developing interpersonal skills provides the flexibility needed to work well with a range of other people, increasing the opportunities for both leadership and followership.

Interpersonal skills include the ability to listen and demonstrate understanding of others' views, display trust, build relationships, and support others. Closely linked with communication and leadership, interpersonal skills allow people to manage conflict effectively, negotiate, advocate their views compellingly, and use power to achieve desired ends. Interpersonal skills are not dependent on a particular set

of personality preferences and styles. Read biographies of both Linus Torvald and Steve Jobs, and you will read portraits of very different men. Interpersonal skills result from self-awareness, the ability to read and empathize with others, and the ability to work with others toward a common goal. While "code may win arguments" in hacker culture, it is the combination of both technical and interpersonal skills that brings people together for the argument in the first place.

Psychological type, popularized through the Myers-Briggs Type Indicator (MBTI), is a popular model in understanding a set of different dimensions of personality that can contribute to interpersonal skills (Myers and Myers, 1980, 1995; Kroeger et al., 2002). Like technical skills, interpersonal skills are teachable, and the psychological type model has helped many professionals understand how their personalities impact behavior and their relationships with others (Peslak, 2006).

The MBTI assesses four dimensions of personality: your source of energy (internal or external); your preference for data gathering (detailed and specific, or abstract and global); your preference for decision making (logical and objective, or subjective and values driven); and your orientation to the world (whether you prefer to show others your decisions or your perceptions) (Kroeger et al., 2002).

Preferences often manifest themselves in behaviors, which can either support or irritate relationships with others. As an example, imagine a developer who is energized by the internal world (rather than engaging with others), and when in the external world, prefers a sense of order, structure, and closure (rather than openness and flexibility). Because this developer prefers to communicate final thoughts in a decision-based format, she expects that others generally operate this way as well. Our developer is in a prototype review session with a user who is energized by the external world, and who prefers to bounce ideas around to explore and learn in real time. This user may view interaction periods as open brainstorming sessions, designed to explore new ideas, cover the possibilities, and think out loud.

What might happen as an outcome of this prototype review session? From the developer's perspective, the meeting resulted in a series of decisions, and a long list of new requirements. From the user's perspective, the discussion was simply the sharing of ideas and options, and alternatives for consideration, no strings attached. This scenario, which is neither exaggerated nor uncommon, is an example of how personality type can impact relationships. It also reframes the enduring problem of requirement creep, a key issue facing the IT community. Requirements creep is usually described as a problem at the system or project level; however, every need ever articulated for a system came from a human user expressing an individual thought. How that thought is heard and managed is ultimately what leads to the project-level problem of requirement creep. This is only one example. Consider the full range of preference combinations between developers and users, and the complexity and potential impact of human dynamics in the development process becomes even more dramatic.

The MBTI is, of course, only one psychological assessment used to study personality and team style and preference, and it is by no means universally accepted. Some, for example, reject the idea of personality testing altogether. Others reject the MBTI based upon reviews of its psychometric characteristics, such as construct validity and applicability (Pittenger, 1993; Capraro and Capraro, 2002).

Other models with associated assessments that provide personality-related insights across different scales include the "Big Five," a generic term for assessments that study the five personality characteristics of extraversion, openness, agreeableness, conscientiousness, and emotional stability (McCrae and John, 1992; Grucza and Goldberg, 2007); EQ indicators, which assess a variety of factors related to self-awareness, self-management, social awareness, and relationship management (Petrides and Furnham, 2000; Stein and Book, 2006); and reversal theory, which assesses motivational states, changeability, and emotion (Apter, 2007; Tucker and Rutledge, 2007).

What is the best practice that can be gained from using psychometric tools? Investing the time and effort to learn about personality preferences, and learning how to recognize them in others yields better relationship management skills and less frustration, because having a language with which to talk about differences makes them easier to resolve. This conclusion is also supported by evidence from a study of 40 software development teams, which concluded "how people work together is a stronger predictor of performance than the individual skills and abilities of team members" (Sawyer, 2001).

29.2.3 Systems Development Life Cycle Models

The previous section touched upon process as a critical element of team dynamics. Process includes systems and software development models. Given their importance, this section considers different systems development life cycle models or methodologies, through the lens of the human-centered demands that they place on a development professional. While there are many overlaps between methods, the presentation here is based upon the type of people-driven factors that tend to be called upon the most for that method type.

29.2.3.1 Formal Structured Methods

Formal structured methods, such as the classic waterfall methodology and the risk-based spiral model, are methods that are generally governed by a plan-driven predictable and repeatable process (McConnell, 1996; Boehm, 1998; Ahren, 2001). In the formal structured methods, development occurs through a series of sequential phases, with a major milestone review marking the end of each phase or iteration. While phases differ across projects and different variations of the development model, they generally cover the following types of activities: concept development or needs assessment, requirements analysis, high-level or general design, detailed design, coding/unit test/debugging, system testing, and implementation. Spiral models add an iterative element to the structure, allowing the team to learn between iterations and the user to see some outcomes, while still maintaining the discipline of structured methods.

Formal structured methods work well for low-speed and low-change projects, in which there is a very clear and stable definition of the requirements, the product, and the supporting technology. It is also used for large projects where high quality, low error outputs must be combined with other engineered systems, or for long-term expensive projects where budget and resource planning is vital to keep the project funded and staffed.

Ultimately, the strengths of any method also hold the source of its weaknesses. The discipline of formal methods can lead to a project that is inflexible to changing needs, and an overemphasis on process documentation can take time away from actual project development. Structured development models are likely to appeal to developers and users who have lower tolerance for ambiguity, enjoy the stability of long-term projects, do not mind formal process and documentation, prefer concrete milestones and metrics, and enjoy the process of creating high-quality code. It can be frustrating for users and developers who want to see tangible outcomes more quickly.

29.2.3.2 Agile and Other Adaptive Methods

Agile, adaptive methods are defined here primarily by their orientation toward user involvement and the degree of change and flexibility encouraged in the development process. Agile methods emphasize interpersonal interactions, communication, customer collaboration, rapid production of code, and frequent feedback (Agile Alliance, 2001; Vinekar et al., 2006; Moe et al., 2010; Stettina and Heijstek, 2011; Thibodeau, 2011). In contrast to formal structured methods, agile development methods have been praised for bringing together developers and users and for allowing fluidity in the development process as participants co-learn and evolve their understanding of the true business needs and requirements.

While agile methods have become widely adopted over the past few years, there are critiques as well (Boehm and Turner, 2004; Dyba and Dingsøyr, 2008; Barlow et al., 2011; Gualtieri, 2011). The bias toward rapid development of code can lead to software modules that solve an immediate problem but that are not built with an eye to the customer organization's business strategies and need for larger-scale integration points. Furthermore, the method is heavily dependent on the presence of knowledgeable users to iterate business requirements in real time. This can lead to solutions that represent the local needs of users that participated in the process, but that may not sufficiently represent the needs of a diverse user base across a larger enterprise.

Agile, adaptive methods require significant interpersonal skills for those engaging frequently with users and comfort with ambiguity, change, and real-time problem solving. It can be frustrating for

those wanting more structure and a broader scope or planning horizon, or for those that are uncomfortable working with users or receiving uncensored feedback in real-time application development environments.

29.2.3.3 Hackathon Method

Some may bristle at the classification of the hackathon as a method, seeing it as an extension of the iterative methods discussed earlier; however, these problem-focused coding approach and events have made a sufficient mark on the programming landscape and culture to be considered separately here. Described as "a contest to pitch, program, and present," (Leckart, 2012) hackathons bring together programmers and systems engineers to work on specific software problems or to compete for funding for further development. A time-bound variation on the long-standing "code and fix" process, hackathons are characterized by their emphasis on real-time, intensive, outcome-driven coding processes, with developers often using preexisting software resources and toolkits to generate a usable product (such as a new app, or new application programming interface) in a time-boxed period.

Hackathons have become a normal activity for many software firms and programs and have even become a practice in government agencies. In the initial public offering documentation for Facebook, Mark Zuckerberg (2012) described the nature of hacking: "Hacking is also an inherently hands-on and active discipline. Instead of debating for days whether a new idea is possible or what the best way to build something is, hackers would rather just prototype something and see what works." At hackathon events, a problem or goal is presented, and a time span defined in which to work. At the end, the best solution is generally selected with some kind of acknowledgement or award.

Hackathons require personality factors such as comfort and skill with working informally with new people in a small team, the ability to quickly extend and extrapolate preexisting code and tools to solve particular problems, the ability to work intensely under time pressure, and the ability to present one's work to others in a compelling way in a short time. Not everyone thrives in these conditions, but these events have proven to be a valuable mechanism by which new software components can be created quickly.

29.3 Research Opportunities and Conclusions

No technical team sets out to develop a system that does not meet user needs. Moreover, no user purposefully sets out to confuse or muddy the requirements that he or she is trying to articulate. In today's environment of mobile apps and social software, human-centered software is user-driven software, and it is becoming common to refer to interactions with software as "experiences." Given this, "experience creators" must be increasingly trained to be aligned with both the tangible and emotional needs of an increasingly technologically savvy user base. Research and education are two vital paths to maximize this alignment.

29.3.1 Research Landscape and Opportunities

To better assess the research opportunities in human-centered systems development, it is useful to review the type of research generally conducted across selected different technologically oriented disciplines interested in this area. Primary fields of interest here include information systems, systems engineering, and human–computer interaction.

Information systems is a broad and interdisciplinary academic field, covering a range of topics related to the processing and management of information: technologically, organizationally, and cognitively. Information systems covers such domains as data and information management, enterprise architecture, project management, infrastructure, systems analysis and design, information strategy, cognitive science, and informatics (Topi et al., 2010; Buckland, 2011). The field of information systems provides a broad social and systems level perspective of the intersection between people, technology, and information.

Systems engineering research is also a vital resource for those interested in human-centered systems development. It focuses on the theory, practice, and methods associated with the development of often large socio-technical systems. In the realm of systems engineering, case-based studies concerning personality and team performance is the research that most closely relates to the content of this chapter.

Human–computer interaction research also addresses topics at the intersection of people and technology, but generally looks at this intersection from the users' perspective, not the developers (Helander, 1997). For example, a search on "human computer interaction emotion" yields multiple articles about the simulation of emotion by computers, and methods for invoking emotions among users, but includes only isolated references to the emotions of information technologists themselves.

Outside these technology-oriented fields, researchers interested in human-centered systems development might look to the fields of organization development, management, and organization and industrial psychology for both theoretical and applied research. Subfields of leadership development, technology innovation, and team dynamics also can yield valuable insights that can be applied to human-centered systems development.

Unfortunately, in many real-world environments, the work of organizational development professionals and IT professionals remains quite distinct, even though they share the same foundational goals of supporting organization change. Organizational development professionals tend to approach problems from the people perspective; IT professionals tend to approach problems from the technical or information flow perspective. The different language and tools used by each type of professional makes cross-fertilization less common in professional settings than one might hope.

Examples of research that would further support the principles and applications presented in this chapter are as follows:

- *Empirically based case studies*: More empirical research using validated psychological assessments is required to solidify the connection between effective human dynamics, communication, and project success. Too often, empirical studies rely not on published and controlled validated assessments (such as the MBTI), but rather, on publically available "spin-offs," which while grounded in the same theories, lack the validity to support confidence in study results.
- *Cross-team comparison studies*: Unfortunately, the lack of standardization between existing studies of personality and team project success makes their results difficult to generalize or to usefully compare findings across projects with different characteristics. More studies using similar methods across well-defined but distinct environments are needed to better understand the intersection of personality preferences, development models, and product outcomes and successes over time.
- *Ethnographic research*: Observational studies of development teams at work, including their interaction with each other and with users, would provide additional ground-level evidence that could inform future practice. For example, comparing the actual content of joint applications development sessions or agile-based user-developer discussions against the final specifications of a completed product could yield useful insights about the types of elicitation techniques or conversational arcs that are most effective in yielding useful requirements and efficient user feedback.

Research helps to support the work of practitioners by providing insight into human-centered systems development and its processes, and cross-disciplinary research helps bridge the existing gaps between computer science and the social sciences. The key, however, is to continue to work to bridge the boundaries between academic communities and industry and government so that the research generated in the academic world is communicated in a way that is practical and useful for nonacademic professionals fighting the fires of delayed and at-risk projects in real time. Collaborative research efforts with industry can also to help unite today's curriculum and students with the industry challenges and opportunities of tomorrow.

29.3.2 Teaching Methods

A focus on human-centered systems development points to several themes for educators to consider in developing curricula for technical professionals. Key competencies to develop in these efforts include

- Self-awareness and learning
- User interaction and communication
- Team dynamics
- Innovation
- Working with ambiguity and uncertainty
- Process management and quality improvement

Encourage a broad curriculum: Educators are in a unique position to help technology professionals experience a broad curriculum that includes interpersonal skills development and learning projects that focus on team-based work (Crawley et al., 2007). Teaching skills such as critical thinking and analysis, writing, strategies to learn new development tools and languages as they emerge, and helping students develop the habits of self-awareness and introspection will serve them well in any professional setting.

Balance theory and practice: Personality type theorists argue that how people perceive or gather information is the most important factor in determining how people learn. Some people learn best when given a theoretical framework within which to place new information. Others learn best when presented with practical applications or when they are able to interact with tools that allow practice and interaction with the new knowledge. Balancing theory and practice develops concrete applications knowledge, while also providing a broad theoretical foundation from which future applications can be derived. Practice also reminds hands-on students why they self-selected into a field in the first place, particularly important for students who selected into the field because of its practical applications and potential for impact.

Incorporate human uncertainty into assignments: Many educators use simulated exercises or case studies to allow programmers to practice programming skills. These methods are even more useful when they integrate real users and user needs into the equation. Projects being completed under the humanitarian free and open source software program are a good example of instances where educators are providing students with real life software development opportunities. These opportunities are not just isolated exercises, but are full life cycle experiences completed over the course of a semester, giving students exposure to a wide range of activities and interactions that they will encounter in the future as professionals (Morelli et al., 2010).

These projects benefit both students and nonprofit organizations; the students gain invaluable exposure and experience, and the users gain a piece of software that supports a humanitarian-focused nonprofit mission. Research related to the long-term impact that these experiences have on students as they enter their careers would be a useful step to validate the usefulness of these experiences over the long term.

29.3.3 Conclusions

Recognizing the human-centered elements of systems development, including personality preferences, team dynamics, and development models, may help technical professionals select projects or roles that support personal values and areas of personal strength. Some people simply would rather work alone to generate a product that later can be joined with the efforts of others. Other people enjoy the shared nature of actively collaborative efforts. Some developers enjoy the iterative nature of evolutionary prototyping; others find the constant change and uncertainty more frustrating than freeing.

Technology professionals should take the time and be given the experiences that allow them to recognize their personal strengths, preferences, and potential blind spots when selecting jobs or projects. If a developer, for example, chafes against the requirements for structure and documentation that come

with working on a project governed by structured methods and capability maturity models, it is better to know this in advance. Research provides useful context for asking new questions, but in the end, self-knowledge is the foundational key to making more effective decisions: decisions that will impact the individual, the development team, and ultimately the end user.

Developing and Managing Complex, Evolving Information Infrastructures

Ole Hanseth
University of Oslo

30.1 Introduction

30.1.1 The Growth of Complexity in ICT Solutions, the Emergence of Information Infrastructures, and the Need for a New Paradigm

Increased processing power and higher transmission and storage capacity have made it possible to build increasingly integrated and versatile information technology (IT) solutions with dramatically increased complexity (BCS/RAE 2004, Hanseth and Ciborra 2007, Kallinikos 2007). The complexity of IT solutions has also been continuously growing as existing systems, new and old, have been increasingly integrated with each other. Complexity can be defined here as the dramatic increase in the number and heterogeneity of included components, relations, and their dynamic and unexpected interactions in IT solutions (c.f. Hanseth and Lyytinen 2010).

The Software Engineering Institute (SEI) at Carnegie-Mellon University describes this trend as the emergence of ultra-large-scale (ULS) systems (Northrop 2006). The report argues that these ULS systems will push far beyond the size of today's systems and systems of systems by every measure:

- Number of technological components of various kinds
- Number of people and organizations employing the system for different purposes

- Number of people and organizations involved in the development, maintenance, and operations of the systems
- Amount of data stored, accessed, manipulated, and refined
- Number of connections and interdependencies among the elements involved

The report argues further that the sheer scale of ULS systems will change everything: ULS systems will necessarily be decentralized in a variety of ways, developed and used by a wide variety of stakeholders with conflicting needs that it will be evolving continuously, and constructed from heterogeneous parts. Further, people will not just be users of a ULS system; they will be elements of the system. The acquisition of a ULS system will be simultaneous with its operation and will require new methods for control. These characteristics are, according to the report, emerging in today's systems of systems; in the near future, they will dominate.

The SEI report states that the scale of ULS systems presents challenges that are unlikely to be addressed adequately by incremental research within the established paradigm. Rather, *they require a broad new conception of both the nature of such systems and new ideas for how to develop them*. We will need to look at them differently, not just as systems or systems of systems, but as socio-technical ecosystems.

The growth in complexity has brought to researchers' attention novel mechanisms to cope with complexity, such as architectures and modularity and standards (Parnas 1972, Schmidt and Werle 1998, Baldwin and Clark 2000). Another, more recent, line of research has adopted a more holistic, socio-technical and evolutionary approach, putting the growth in the combined social and technical complexity at the centre of an empirical scrutiny (see, e.g., Edwards et al. 2007). These scholars view these complex systems as new types of IT artifacts and denote them with a generic label of information infrastructures (IIs) (e.g., Star and Ruhleder 1996, Hanseth and Lyytinen 2010, Tilson et al. 2010).

Hanseth and Lyytinen (2010) define an II, consistent with the aforementioned characterization of ULS, as a shared, open (and unbounded), heterogeneous, and evolving socio-technical system (called installed base) consisting of a set of IT capabilities and their users, operations, and design communities. Typical examples of IIs are the Internet, solutions supporting the interaction among manufacturers along a supply chain, and portfolios of integrated applications in organizations.

30.1.2 Key Characteristics of IIs

The most distinctive feature of IIs and ULSs is their overall complexity. Managing IIs, then, is about understanding and managing complexity. More specifically: IIs, like all complex systems, are evolving and not designed from scratch. So managing IIs means managing their evolution.

IIs are radically different from how information and software systems are presented in the literature. Infrastructures have no life cycle—they are "always already present." This is strictly true of some infrastructures, such as our road infrastructure that has evolved through modifications and extensions ever since animals created the first paths. IT infrastructures certainly have a much shorter history, but an II like the Internet has now been around and constantly evolving for roughly 40 years. The same is the case for IIs like portfolios of integrated information system (IS) (often numbering in the thousands) in larger organizations. Developing IIs, then, requires approaches that are different from the traditional "design from scratch" ones (Edwards et al. 2007, Hanseth and Lyytinen 2010, Tilson et al. 2010). It requires somewhat opposite approaches—it is about modifying (changing and extending) the installed base, existing IIs, so that the installed base evolves as far as possible toward what is desired (user requirements).

The evolution of IIs involves regularly a large number of actors. All these actors cannot be strictly controlled from one single point (like, for instance, a manager at the top of a hierarchically structured project organization). They will often act independently. In the case of the Internet, there are thousands, if not millions, of actors developing new services of the top of the Internet or adding new features to lower level services, like, for example, quality of service mechanisms. This means that even though there

are many institutions (like ICANN, IETF, etc.) that are involved in the governance of the Internet, the Internet is not evolving in strictly planned or controlled way. Its evolution is mostly the aggregated result of the various autonomous actors' actions. Institutions having responsibility for the governance of the Internet can have impact and shape its evolution in a way similar to how we may influence the growth of an organism or a piece of land. The same is the case for large application portfolios. The individual applications and their relations (degree of integration) will change continuously, and no single actor will have a total overview of these changes. Accordingly, we call our approach to how we can shape the evolution of an II "*installed base cultivation*" (Hanseth and Lyytinen 2010).

If infrastructures are "always already present," are new infrastructures never emerging? Was not the Internet a new infrastructure at some point in time? Yes, of course. New IIs are indeed emerging. It happens primarily in two ways. One, a system may be growing in terms of number of users and along that path gradually changing from being a system (or application) of limited reach and range into a large scale II. E-mail, for instance, was introduced into the Internet (or rather the Arpanet) at a time when the net consisted of only four computers. Those computers (and the e-mail service) did not constitute an II, but a distributed system of limited complexity. But as the net was growing in terms of computers connected, services, developers, and users, it was taking on more and more the character of an infrastructure. The other way an II may emerge has been seen in most large organizations. Over time, the number of applications has continuously been growing at the same time as old and new applications have been increasingly more integrated. During this process, the application portfolio is growing from the first stand-alone one to a few loosely integrated ones and toward an increasingly more complex II.

The next section will present theories of complexity that help us understand the dynamics of IIs followed by a section giving a brief outline of what I see as the key challenges related to the management of the evolution of IIs and what kind of "tools" that are available for this task. Finally, I will present three examples of II evolution and how the choices of strategy and management tools have shaped the evolution of these IIs.

30.2 Socio-Technical Complexity and Theories of Complexity

In this section, I will present three theories of complexity that help us understand the core issues related to IIs.

30.2.1 Actor Network Theory

Actor network theory (ANT) was originally developed as a "toolbox" for studying processes from individual experiments to a situation where scientific facts or theories are universally accepted as such. This "toolbox" consists of a set of concepts for describing how relations between elements of various kinds are established in a process where heterogeneous networks are constructed. Central concepts in early ANT research are closure, enrolment, and alignment. Specifically, closure indicates a state where consensus emerges around a particular technology. Closure stabilizes the technology by accumulating resistance against change. It is achieved through a negotiation process and by enrolling actors/elements of various kinds into a network and translating (re-interpreting or changing) them so that the elements are aligned, that is, fit together, in a way that supports the designers' intentions.

The early ANT studies can be said to have focused on complexity in the sense that they spelled out the rich and complex relations between the scientific and the technological on the one hand, and the social on the other, related to the making of scientific theories and technological solutions. ANT has been used, for instance, in research on the negotiation of IS standards and the embedding of their local context of development and use (Star and Ruhleder 1996, Hanseth and Monteiro 1997, Timmermans and Berg 1997, Bowker and Star 1999, Fomin et al. 2003).

Since their emergence in the early 1980s, ANT and ANT research have evolved beyond their (so-called) "managerial" approach, which focuses on how a single actor-network is aligned by a dominating central

actor (Law 2003b). Complexity has been addressed more explicitly as the focus has turned to the dynamics unfolding when independent actors try to align different but intersected actor-networks (Latour 1988, Star and Griesemer 1989, Law and Mol 2004, Law and Urry 2004, Law 2003a). This has happened as attention has moved toward more complex cases where order and universality cannot be achieved in the classical way.* These cases are described as "worlds," which are too complex to be closed and ordered according to one single mode or logic. There will only be partial orders, which are interacting in different ways, or interconnected and overlapping subworlds, which are ordered according to different logics. The interconnectedness of the subworlds means that when one is trying to make order in one subworld by imposing a specific logic, the same logic is making disorder in another—an order also has its disorder (Berg and Timmermans 2000, Law 2003b). Rather than alignment, stabilization, and closure, the keywords are now *multiplicities, inconsistencies, ambivalence, ambiguities, and fluids* (Law and Mol 2002, Law 2003a). Mastering this new world is not about achieving stabilization and closure, but rather about more ad hoc practices—"ontological choreography" of an ontological patchwork (Cussins 1998). This approach has been applied to studies of cases such as train accidents (Law 2003a), a broad range of high-tech medical practices (Mol and Berg 1998), and interdisciplinary research (Star and Griesemer 1989). This approach to complexity has also been applied to analyzing the challenges, not to say impossibility, of achieving closure and stabilization in relation to IIs and ICT standards (Aanestad and Hanseth 2000, Alphonse and Hanseth 2010).

30.2.2 Complexity Science

Just like the ANT community, the emergence of order has been in focus within the field of complexity science. However, while the first has focused on order making where humans are actively involved, the latter has had a focus on how order emerges without any "intelligent designer" involved like, for instance, the order found in complex organisms and "animal societies" like bee hives and ant heaps. But important contributions to complexity science have been made from studies of more social phenomena, in particular within the economy, like financial markets and also, an issue central to this book, standardization (David 1986, Arthur 1994). Complexity science is made up of a broad range of disciplines such as chaos theory and complex adaptive systems (CAS). CAS is concerned with the dynamic with which complex systems evolve through adaptation and is increasingly used in organizational studies, for example, in health care. CAS is made up of semiautonomous agents with the inherent ability to change and adapt to other agents and to the environment (Holland 1995). Agents can be grouped, or aggregated into meta-agents, and these can be part of a hierarchical arrangement of levels of agents. Agents can respond to stimuli—they behave according to a set of rules (schema).

Adaptation is the process whereby the agent fits into the environment and the agent as well as the CAS undergoes change. Adaptation—and creativity and innovation—is seen as being optimal at "the edge of chaos" (Stacey 1996), or more generally, adaptation occurs within the zone of complexity, which is located between the zone of stasis and the zone of chaos (Eoyang 1996). Dooley (1996) suggests that CAS behave according to three principles: order is emergent, the system's history is irreversible, and the system's future is unpredictable.

Overall, complexity science investigates systems that *adapt* and *evolve* as they *self-organize* through *time* (Urry 2003). Central to the emergence of orders are *attractors*, that is, a limited range of possible states within which the system stabilizes. The simplest attractor is a single point. There are also attractors with specific shapes, which are called "strange attractors," that is, unstable spaces to which the trajectory of dynamical systems are attracted through millions of iterations" (Capra 1996).

* John Law and Annamarie Mol (2002, p. 1) define complexity as follows: "There is complexity if things relate but don't add up, if events occur but not within the process of linear time, and if phenomena share a space but cannot be mapped in terms of a single set of three-dimensional coordinates." This definition is very brief and rather abstract, but is in perfect harmony with Cillier's definition presented earlier.

Orders emerge around attractors through various *feedback* mechanisms, including *increasing returns*, and through *path-dependent* processes of many small steps that may end in *lock-in* situations (David 1986). Some steps may be crucial in the sense that they may force the process in radically different (unexpected) directions. Such points are called tipping or bifurcation points (Akerlof 1970). The existence of such points makes the evolution of complex systems *nonlinear* in the sense that small changes in a system at one point in time may lead to hugely different consequences at a later point in time. Many of these concepts have been presented to the IS community by Shapiro and Varian (1999) under the label information economy. They will be explained in the subsequent sections.

30.2.2.1 Increasing Returns and Positive Feedback

Increasing returns mean that the more a particular product is produced, sold, or used, the more valuable or profitable it becomes. Infrastructure standards are paradigm examples of products having this characteristic. The development and diffusion of infrastructural technologies are determined by "the overriding importance of standards and the installed base compared to conventional strategies concentrating on programme quality and other promotional efforts" (Grindley 1995: 7).

A communication standard's value is to a large extent determined by the number of users using it—that is, the number of users you can communicate with if you adopt the standard. This phenomenon is illustrated by well-known examples such as Microsoft Windows and the rapid diffusion of the Internet. Earlier examples are the sustainability of FORTRAN and COBOL far beyond the time when they had become technologically outdated.

The basic mechanism is that the large installed base attracts complementary products and makes the standard cumulatively more attractive. A larger base with more complementary products also increases the credibility of the standard. Together these make a standard more attractive to new users. This brings in more adoptions, which further increases the size of the installed base, and so on (Grindley 1995: 27).

Further, there is a strong connection between increasing-returns mechanisms and *learning* processes. Increased production brings additional benefits: producing more units means gaining more experience in the manufacturing process, achieving greater understanding of how to produce additional products even more cheaply. Moreover, *experience* gained with one product or technology can make it easier to produce new products incorporating similar or related technologies. Accordingly, Shapiro and Varian (1999) see positive feedback as the central element in the information economy, defining information as anything that may be digitized. An information good involves high fixed costs but low marginal costs. The cost of producing the first copy of an information good may be substantial, but the cost of producing (or reproducing) additional copies is negligible. They argue that the key concept in the network economy is positive feedback.

30.2.2.2 Network Externalities

Whether real or virtual, networks have a fundamental economic characteristic: The value of connecting to a network depends on the number of other people already connected to it. This fundamental value proposition goes under many names: Network effects, network externalities, and demand-side economies of scale. They all refer to essentially the same point: Other things being equal, it is better to be connected to a bigger network than a smaller one (Shapiro and Varian 1999.)

Externalities arise when one market participant affects others without compensation being paid. In general, network externalities may cause negative as well as positive effects. The classic example of negative externalities is pollution: My sewage ruins your swimming or drinking water. Positive externalities give rise to positive feedback (Shapiro and Varian 1999).

30.2.2.3 Path Dependency

Network externalities and positive feedback give rise to a number of more specific effects. One such is *path dependence*. Path dependence means that past events will have large impacts on future development, and events that appear to be irrelevant may turn out to have tremendous effects (David 1986).

For instance, a standard that builds up an installed base ahead of its competitors becomes cumulatively more attractive, making the choice of standards "path dependent" and highly influenced by a small advantage gained in the early stages (Grindley 1995: 2). The classical and widely known example illustrating this phenomenon is the development and evolution of keyboard layouts, leading to the development and *de facto* standardization of QWERTY (David 1986).

We can distinguish between two forms of path dependence:

1. Early advantage in terms of numbers of users leads to victory
2. Early decisions concerning the design of the technology will influence future design decisions

The first one has already been mentioned earlier. When two technologies of a kind where standards are important—such as communication protocols or operating systems—are competing, the one getting an early lead in terms of number of users becomes more valuable for the users. This may attract more users to this technology, and it may win the competition and become a *de facto* standard. The establishment of Microsoft Windows as the standard operating system for PCs followed this pattern. The same pattern was also followed by the Internet protocols during the period they were competing with OSI protocols.

The second form of path dependence concerns the technical design of a technology. When, for instance, a technology is established as a standard, new versions of the technology must be designed in a way that is compatible (in one way or another) with the existing installed base. This implies that design decisions made early in the history of a technology will often live with the technology as long as it exists. Typical examples of this are various technologies struggling with the backward compatibility problem. Well-known examples in this respect are the different generations of Intel's microprocessors, where all later versions are compatible with the 8086 processor, which was introduced into the market around 1982.

Early decisions about the design of the Internet technology, for instance, have had a considerable impact on the design of new solutions both to improve existing services and to add new ones to the Internet. For example, the design of the TCP/IP protocol constrains how improved solutions concerning real-time multimedia transfer can be designed and how security and accounting services can be added to the current Internet.

30.2.2.4 Lock-In: Switching Costs and Coordination Problems

Increasing return may lead to yet another effect: *lock-in*. Lock-in means that after a technology has been adopted, it will be very hard or impossible to develop competing technologies. "Once random economic events select a particular path, the choice becomes locked-in regardless of the advantages of alternatives" (Arthur 1994). In general, lock-in arises whenever users invest in multiple complementary and durable assets specific to a particular technology. We can identify different types of lock-in: contractual commitments, durable purchases, brand-specific training, information and databases, specialized suppliers, search costs, and loyalty programmes (Shapiro and Varian 1999). We can also say that lock-ins are caused by the huge switching costs or by coordination problems (or a combination of these) that would be incurred when switching from one standardized technology to another.

Switching costs and lock-ins are ubiquitous in ISs, and managing these costs is very tricky both for sellers and buyers. For most of the history of computers, customers have been in a position where they could not avoid buying (more or less) all their equipment and software from the same vendor. The switching costs of changing computer systems could have been astronomical—and certainly so high that no organization did. To change from one manufacturer (standard) to another would imply changing all equipment and applications at the same time. This would be very expensive—far beyond what anybody could afford. But it would also be an enormous waste of resources, because the investments made have differing economic lifetimes, so there is no easy time to start using a new, incompatible system. As a result, others face switching costs, which effectively lock them into their current system or brand (Shapiro and Varian 1999).

Switching costs also go beyond the amount of money an organization has to pay to acquire a new technology and install it. Since many software systems are mission critical, the risks in using a new vendor, especially an unproven one, are substantial. Switching costs for customers include the risk of a severe disruption in operations.

Lock-in is not only created by hardware and software. Information itself—its structures in databases as well as the semantics of the individual data elements—is linked together into huge and complex networks that create lock-ins. One of the distinct features of information-based lock-in is that it proves to be so durable: equipment wears out, reducing switching costs, but specialized databases live on and grow, increasing lock-in over time (Shapiro and Varian 1999).

The examples of lock-ins and switching costs mentioned so far are all related to infrastructures that are seen as local to one organization. As infrastructures and standards are shared across organizations, lock-in problems become even more challenging.

Network externalities make it virtually impossible for a small network to thrive. But every network has to start from scratch. The challenge to companies introducing new but incompatible technology into the market is to build a network size that overcomes the collective switching costs—that is, the combined switching costs of all users. In many information industries, collective switching costs are the biggest single force working in favor of incumbents. Worse yet for would-be entrants and innovators, switching costs work in a nonlinear way: Convincing 10 people connected in a network to switch to your technology is more than 10 times as hard as getting one customer to switch. But you need all 10, or most of them: No one will want to be the first to give up the network externalities and risk being stranded. Precisely because various users find it so difficult to coordinate a switch to an incompatible technology, control over a large installed base of users can be the greatest asset you can have.

But lock-in is more than cost. As the community using the same technology or standard grows, switching to a new technology or standard becomes an increasingly larger *coordination* challenge. The lock-in represented by QWERTY, for instance, is most of all a coordination issue. It is shown that the individual costs of switching are marginal (David 1986), but, as long as we expect others to stick to the standard, it is best that we do so ourselves as well. There are too many users (everybody using a typewriter or PC/computer). It is impossible to bring them together so that they could agree on a new standard and commit themselves to switch.

30.2.2.4.1 Inefficiency

The last consequence of positive feedback we mention is what is called *possible inefficiency*. This means that the best solution will not necessarily win. An illustrative and well-known example of this phenomenon is the competition between the Microsoft Windows operating system and Macintosh. Macintosh was widely held to be the best technology—in particular from a user point of view—but Windows won because it had early succeeded in building a large installed base.

30.2.3 World Risk Society and Reflexive Modernization

Ulrich Beck provides an extensive analysis of the essence and impact of globalization processes. IIs, such as the Internet, are key elements in globalization processes at the same time as globalization generates increased demands for more globally distributed and integrated IIs. The key element in Beck's argument is that globalization radically changes our possibilities for controlling processes in nature and society, and then also the conditions and possibilities for managing IIs. The reason for this is, in short, the growth in complexity produced by globalization.

Beck builds his theory of (World) Risk Society on a distinction between what he calls first and second modernity. First modernity is based on nation-state societies, where social relations, networks, and communities are understood in a territorial sense. He argues further that the collective patterns of life, progress and controllability, full employment, and exploitation of nature that were typical in this first modernity have now been undermined by five interlinked processes: globalization, individualization,

gender revolution, underemployment, and global risks. The kind of risks he primarily focuses on is those related to the ecological crises (climate change) and global financial markets.

At the same time, as the risks are becoming global, their origin is also globalization (Beck 1986, 1999, Giddens 1990, Beck et al. 1994). And, further, both on-going globalization processes as well as the outcome—that is, increased risks—are fundamentally related to modernity. Globalization is the form modernization has taken today, and risks are increasing because of the changing nature of modernity. The very idea of controllability, certainty, and security—which was so fundamental in the first modernity—collapses in the transfer to second modernity (Beck 1999, p. 2). Modernity's aim has been to increase our ability to control processes in nature and society in a better way through increased knowledge and improved technology. The concept of "world risk society" draws our attention to the limited controllability of the dangers we have created for ourselves. The reflexive modernization argument (at least in Beck's version) says that while it has been the case that increased modernization implied increased control, in second modernity, modernization, that is, enhanced technologies and an increase in bodies of knowledge, may lead to less control, that is, higher risks.

This is what lies at the heart of the "reflexivity" argument. In particular, the theory of reflexive modernization contradicts the instrumental optimism regarding the predetermined controllability of uncontrollable things: "the thesis that more knowledge about social life… equals greater control over our fate is false" (Giddens 1990: 43), and "the expansion and heightening of the intention of control ultimately ends up producing the opposite" (Beck et al. 1994: 9).

This shift, which may appear contradictory, can be explained by *the ubiquitous role of side effects*. Modernization means integration. At the same time, all changes and actions—new technologies introduced, organizational structures and work procedures implemented, and so on—have unintended side effects. The more integrated the world becomes, the longer and faster side effects travel, and the heavier their consequences. Globalization, then, means globalization of side effects. In Beck et al.'s (1994: 175, 181) own words: "It is not knowledge but rather non-knowledge that is the medium of reflexive modernization… we are living in the age of side effects… The side effect, not instrumental rationality, is becoming the motor of social change."

The theories of Risk Society and Reflexive Modernization can be seen as complexity theories in the sense that complexity is at their core. Seeing globalization as an integration process, for instance, can very well lead to it also being seen as a process of making the world more complex exactly through this integration process. The role attributed to side effects also links naturally to complexity. The role of side effects is increasing exactly because the "system" is becoming so complex. Because of its complexity, we cannot know how all components are interacting; accordingly, the outcomes of those interactions will be more unpredictable.

30.3 Design Challenges and Management "Tools"

30.3.1 Design Dilemmas

30.3.1.1 Tension between Standards and Flexibility

Infrastructures are made up of a huge number of components. Accordingly, standards defining the interfaces between components are essential features of IIs, and the specification and implementation of standards are important activities in the establishment of IIs. Standards are closely associated with stability. This is the case partly because keeping a standard stable is required for various reasons (e.g., data standards that make it possible to store data today and read them at a later time). But standards are also stable because widely diffused standards are so hard to change when we have to (because of the lock-in problem). However, standards need the change over time. Just like ISs, IIs need to change and adapt to changing user requirements. And some such changes mean that implemented standards need to change, too. At the same time, the scaling and growth of an II can generate need for changes in standards even though user requirements stay unchanged (Hanseth et al. 1996, Tilson et al. 2010).

Accordingly, IIs will evolve as a dynamic driven by a tension between standards (stability and uniformity) and flexibility (change and heterogeneity). Managing this tension is a key to the management of IIs (Hanseth et al. 1996).

30.3.1.2 Bootstrapping—Adaptability

The dynamic complexity of IIs poses a chicken–egg problem for the II designer that has been largely ignored in the traditional approaches. On one hand, IT capabilities embedded in IIs gain their value, as explained earlier, by being used by a large number of users demanding rapid growth in the user. Therefore, II designers have to come up early on with solutions that persuade users to adopt while the user community is non-existent or small. This requires II designers to address head on the needs of the very first users before addressing completeness of their design or scalability. This can be difficult, however, because II designers must also anticipate the completeness of their designs. This defines the *bootstrap problem of II design*. On the other hand, when the II starts expanding by benefitting from the network effects, it will switch to a period of rapid growth. During this growth, designers need to heed for unforeseen and diverse demands and produce designs that cope technically and socially with these increasingly varying needs. This demands infrastructural flexibility in that the II adapts technically and socially. This defines the *adaptability problem of II design* (Edwards et al. 2007, Hanseth and Lyytinen 2010). Clearly, these two demands contradict and generate tensions at any point of time in II design (Edwards et al. 2007).

30.3.2 Management "Tools"

So what kinds of "tools" are available for managing the evolution of IIs—or for installed base cultivation? The answer given here is: *process strategy*, *architecture*, and *governance regime*. The rationale behind the focus on these three aspects is, first of all, the fact that these three "tools" are what development efforts are all about: the steps to be taken to develop some new technology (bottom-up or top-down, incremental/iterative or "big-bang," evolutionary and learning driven or specification driven, etc.); the architecture and overall design of the technology (the modularization of a system determines how and how easy it may be maintained and modified); and how to govern, manage, and organize the effort. In addition, these "tools" have also been at the centre of extensive discussions and research on the evolution of the Internet. These three factors have been three aspects as key factors behind its success: an experimental bottom-up development strategy (which includes a strategy and rules for bottom-up development and settlement of standards), the end-to-end architecture, and distributed control and governance structures combined with open source software licenses (Hanseth et al. 1996, Benkler 2006, Zittrain 2006).

Traditionally, the management of ICT has focused on the management of projects developing ICT solutions. Such projects are typically organized as a hierarchy of subprojects each with a subproject manager. Each manager has the rights to make decisions within the domain of the subprojects and give instructions to the managers at the level below. The management of such a project organization is normally supported by various management tools such as the detailed plans and establishment of milestones. And further, the production of detailed plans and the monitoring of the progress made in the project—if it is progressing according to the plan or not—are supported by various computer based project management tools. Together this package of project organization, decision rights, and management tools is an example of what I call governance regime. Governing the complexity of IIs requires new and different governance regimes. In the case of the Internet, for example, its successful evolution has been shaped by a governance regime consisting of a few central institutions like IETF and ICANN. Another important part of this regime has been the fact that most of its technology has been distributed based on open source license (like the GNU Public License). But may be the most important elements of the governance regime has been the organizing of the development activities as a loosely connected network of individuals that coordinate their work through extensive use of e-mail and by making all software and relevant information publicly available on FTP and Web servers.

Software and IS development often takes place by following specific methodologies. The central element of such methodologies is a specification of which steps to be taken, and in which sequence, to develop a specific IS solution. This is what I call a process strategy. The complexity of IIs requires process strategies different of those prescribed for traditional IS development efforts. In particular, we need process strategies that address the role of network externalities and path dependence; that is, we need strategies that address the bootstrap and adaptability problems.

The architecture of an IS is traditionally considered important for its maintenance. In general, modularization is an important strategy for coping with complexity. And in the case of IIs, the architecture plays a crucial role. This is illustrated with the role attributed to the Internet's architecture in explaining its successful evolution. The Internet's so-called end-to-end architecture (the functionality is located in the ends of the network, i.e., in the computers connected to the Internet, and not in the network itself, which has been the case within traditional telecommunication networks) has made the Internet extremely flexible in the sense that anybody having a computer connected to the Internet could develop and provide new services.

The management of IIs, then, requires process strategies, architectures, and governance regimes that in combination make an II evolve along the desired path. Exactly which combinations that is appropriate for specific IIs is still a major research issue.

30.4 Three Examples of Evolving IIs

I will here present three examples of IIs. They are all from the health care sector. They are presented as individual and separate IIs, but in reality, they will be linked together and with others and, accordingly, be parts of larger scale IIs in the health care sector. These examples illustrate the variety among IIs and, most importantly, how specific process strategies, architectures, and governance regimes are interacting and shaping the evolution of IIs.

30.4.1 Electronic Patient Records

30.4.1.1 Case Presentation

The introduction of electronic patient record (EPR) systems in hospitals is intended to improve the quality of patient care by replacing the existing fragmented and often unavailable paper-based patient records by an electronic one which would make any information instantly available to anybody, anywhere, and anytime. In 1996, the Medakis project was established with the aim to develop and implement an EPR system in all the five largest hospitals in Norway. Siemens was involved to take care of the software development. The system was given the name DocuLive. We focus here on the implementation at "Rikshospitalet" (see Hanseth et al. 2006), where DocuLive was intended to serve several ambitions: It should include all clinical patient information, covering the needs of all users; it should be built as one single integrated system; it should enable better collaboration and coordination of patient treatment and care through electronic information sharing and exchange. Finally, a more general and important aim, in the contexts of the arguments developed in this paper, was that the system should be a standard EPR solution for all Norwegian hospitals. This was an important goal for two reasons: enable information exchange and making it possible for health care personnel to use the EPR system without training when they are moving from one hospital to another. The deadline set for the delivery of the final system was the end of 1999. The project started with the best intentions of involving users, acknowledging current work practices, and favoring a bottom-up development strategy. However, as we illustrate in the subsequent sections, the difficulties associated with the standardization of both technology and work practices were dramatically underestimated.

Shortly after it began, project members became aware that within Siemens EPR projects were also underway in Sweden, the United Kingdom, Germany, and India. Moreover, they realized that the Norwegian project was not at the top of Siemens' priorities since Norway represented the smallest market.

This meant there was a high risk of overrun as Siemens prioritized more profitable markets. As a consequence, the project members decided to make moves toward "internationalizing" the project, first to the Scandinavian level and later to the European one. However, this decision weakened the consortium's position with respect to Siemens, since now the requirements from all projects from across countries would need to be merged and a new architecture designed.

In 1999, Siemens acquired a large U.S. software company developing software solutions for health care. As a consequence, Siemens' medical division's headquarters was moved from Europe to the United States, and the project's scope became global. As the number of involved users grew, large-scale participatory development became unmanageable. After a few years, only a small number of user representatives from each hospital continued to actively participate in the development. Moreover, the need to continuously find common agreements between the hospitals turned the intended bottom-up approach into a top-down one.

Also, the efforts aimed at solving the fragmentation problem with a complete and smoothly integrated EPR system turned out to be more challenging than foreseen. Paradoxically, the volume of paper records increased, and the patient record became even more fragmented for a variety of reasons. First, this was because new laws on medical documentation required detailed records from professional groups not previously obliged to maintain a record (such as nurses, physiotherapists, and social workers). Second, for both practical and legal reasons, the hospital had to keep updated versions of the complete record. As long as lots of information only existed on paper, the complete record had to be paper-based. Thus, each time a clinical note was written in the EPR, a paper copy was also printed and added to the paper record. Printout efficiency was not a design principle for the current EPR, causing non-adjustable print layouts that could result in two printed pages for one electronic page form. Third, multiple printouts of preliminary documents (e.g., laboratory test results) were often stored in addition to final versions. The result was that the volume of paper documents increased. This growth created a crisis at the paper record archival department. The hospital had moved into new facilities designed with a reduced space for the archive as it was supposed to handle electronic records only. In 2003, the archive was full, and more than 300 shelf meters of records were lying on the floors. This situation also affected the time needed to find records, and often requests failed to be satisfied.

When the implementation of DocuLive started, five local systems containing clinical patient information existed. The plan was to replace these with DocuLive so as to have the EPR as one single integrated IS. In spite of this, the number of local systems was growing at an accelerating speed, based on well-justified needs of the different medical specialties and departments. For example, the in vitro fertilization clinic needed a system that allowed them to consider a couple as a unit, as well as allow tracking of information from both semen and egg quality tests through all procedures involved, up to the birth of the child. The intensive care unit acquired a system that allowed them to harvest digital data from a vast array of medical equipment and thus eliminate the specialized paper forms previously used to document events and actions. Moreover, new digital instruments in use in many different departments include software components with medical record functionality. The number of such specialized systems had grown from 5 in 1996 to 135 in 2003.

The original plan said that the final system should be delivered in 1999. Four years later, toward the end of 2003, the version of DocuLive in use included information types covering between 30% and 40% of a patient record. This meant that the paper records were still very important, but unfortunately more fragmented and inaccessible than ever. The increased fragmentation was partly due to not only the large volume of paper caused by DocuLive printouts but also the high number of specialized systems containing clinical patient information.

At Rikshospitalet they decided to change their strategy and approach complexity in quite different way in 2004. They realized that the idea of one complete EPR system had failed. Instead, they decided to "loosely couple" the various systems containing clinical patient information underneath a "clinical portal" giving each user group access to the relevant information in a coherent way.

30.4.1.2 Another EPR Case

I will here briefly present another EPR case as a contrast to the aforementioned one. Around the same time as the Medakis project started, a small and simple application supporting a few work tasks for a couple of medical doctors was developed by a software developer at a smaller hospital in Northern Norway. The users were very happy with the system. After a period of use, they asked for some added functionality, which was implemented. At the same time, other users became aware of the system and wanted to try using it as a tool supporting some of their work tasks. This was the first iteration of a long evolutionary process. The functionality, number of users, and developers involved started to grow. After a few years, the software and the developers were taken over by a company set up for this task. The company and the software product was given the name DIPS. It has continuously been growing and is today standard EPR system in Norway (Ellingsen and Monteiro 2008). In September 2012, the Oslo University Hospital (which Rikshospitalet is a part of) decided to replace DocuLive with DIPS. This means that four of the five hospitals involved in the Medakis project will have abandoned DocuLive in favor of DIPS.

30.4.1.3 Case Analysis

How can the project trajectory of DocuLive at Rikshospitalet be analyzed? Key issues are the complexities involved and the handling of these complexities. The complexity of the Medakis project and the DocuLive system was made up of a mix of technical, organizational, and medical issues—that is, a very complex actor-network. Further, this case demonstrates the limitations of traditional strategies for managing software development projects and how these strategies lead to actions triggering lots of side effects. These side effects are propagating throughout the actor-network, creating domino- and boomerang effects, which are returning to the origin of the initial actions so that the final results became opposite to what one aimed for. In this way, the case demonstrates the relevance of the theory of reflexive modernization in the sense that strategies aiming at control of the development process leads to less control.

The primary complexity involved is that of the work practices related to patient treatment and care. By trying to make one integrated system that should cover the needs of all hospitals in Norway, one brings together the total complexity of these practices. The hospitals realized that dealing with this was demanding. Accordingly, they concluded that they had to involve a supplier that was strong both financially and in terms of ICT competence. So Siemens was chosen. But then, the complexity of Siemens was merged with that of the hospitals. The medical division within Siemens is large, with a traditional base within medical imaging technologies. The imagining instruments had become digital, and supplementary software systems had been built. As the EPR development activities were increasing within Siemens, it became more and more important to align and integrate the EPR strategy and product(s) with other Siemens products and strategies.

Within this world, Norway become marginal, as the appetite for larger markets escalated in a self-feeding process. A side effect of the expansion of ambitions and scope was the increased complexity: the larger the market Siemens was aiming at, the more diverse the user requirements, and accordingly, the more complex the system had to be in order to satisfy them. This implied that the development costs were growing, which again implied that a larger market was required to make the whole project profitable. The project went through this spiral of self-reinforcing and escalating complexity several times until it collapsed.*

The failure of DocuLive can be explained in more theoretical terms as a failure in attempting to control complexity. Arguably, the main mistake was to follow a "traditional" IS development approach—typical

* At Rokshospitalet, they decided in 2003 to change their strategy quite dramatically. In this new strategy, the central element was loose coupling of the various systems through a portal, which was giving various user groups coherent interfaces to the systems they needed to access. This strategy has been much more successful—but not without its own challenges.

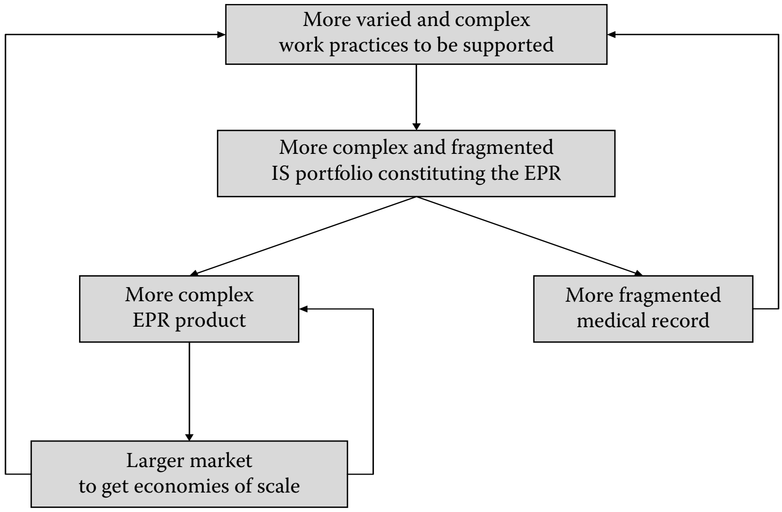

FIGURE 30.1 The reflexive standardization process.

for (first) modernity, that is, overemphasizing criteria of universality, uniformity, and centralization of control to achieve alignment, stabilization, and closure. In line with the more recent developments within actor network theory, our case data suggest that the complexity defines II development as the emergence of multiplicities, inconsistencies, ambivalence, and ambiguities (Law and Mol 2002, Law 2003b). Ironically, what happened became the opposite of the initial aims. When actors tried to stabilize the requirement and design specification by enrolling more actors, this made it less stable. Attempts to improve fragmented records by means of one integrated EPR made the records more fragmented. The complexity of DocuLive turned out to be one where the ordering efforts created disorders. The side effects triggered new ones, which again were reflected back on the origin—the standardization process turned out to be reflexive and self-destructive. The dynamics of reflexive processes at work are summarized in Figure 30.1.

The concept of reflexivity offers thus an interpretation of the dynamics of the case. The theory of "high" modernity helps to observe how the logics of the "first" industrial modernity find their limits (Beck et al. 1994). The intensified interconnectedness of social practices with technical artifacts on the one hand, and the need to align geographically dispersed actors on the other hand, effectively undermines the reductionist approach to control complexity. The weaknesses of such approach become visible when the control itself reflexively reproduced the complexity—thus creating the immanent paradox of modernity. This fact highlights the need to develop alternative standardization approaches that better overcome the paradoxes to deal with complexity.

The case is also an example of self-reinforcing processes driving the dynamics of complex systems. In this case, what the most salient self-reinforcing process is that of the escalation of the complexity.

I will now zoom in a bit more on the specific "management tools" chosen and their impact on the evolution of the DocuLive solution and the Medakis project. Most important is the principal architectural decision made: The solution should be a tightly integrated (or rather monolithic) one. On this basis, it was decided to organize the development activities as a classical hierarchical organization controlled from the top by a project manager and to develop the solution according to a top-down, specification-driven process. The choice of process strategy and governance regime was largely given by the choice of architecture. The important role played by the architecture is illustrated by Rikshospitalet's decision to switch to the almost exact opposite strategy in 2004, that is, an architecture allowing the implementation and use of a large number of applications loosely coupled through a portal. This strategy, then, implied a more evolutionary approach (i.e., process strategy) to the development of individual

applications as well as the overall II, and this evolutionary process was managed by means of a network oriented governance structure in terms of a number of loosely coupled projects. This strategy turned out to be much more successful, and the paper-based patient record was replaced within a couple of years.

The history of DIPS is almost the exact opposite of the Medakis project and DocuLive. It started out as a very small and simple solution design to support a very narrow range of works tasks and very few users. The very first step taken was successful. Learning from and capitalizing on this, the solution has been growing into a national Norwegian EPR II. This process strategy illustrates very well how IIs may bootstrap: as the installed base of an II grows, the use value of the II increases which, in turn, attracts more users in a self-reinforcing spiral. The architecture of DIPS, however, shares its basic features with DocuLive: it is a tightly coupled system. But the bottom-up evolutionary process strategy chosen made it possible to make the solution over time grow into one satisfying the required range of user requirements of a national II. The governance regimes have some common features (proprietary software delivered by a commercial company), but are also different in important areas. The Medakis project was set up as a national and hierarchical organization including representatives from each of the five hospitals. The DIPS governance regime had a more entrepreneurial flavor. The strategy for how a DIPS-based II should grow toward a national one has been determined by the company. User organizations have primarily been involved as customers and as individual hospitals (later regional companies) related to individual implementation projects at each hospital.

30.4.2 Information Exchange between Health Care Institutions

30.4.2.1 Case Presentation

The second case presented is an example of an II supporting information exchange between health care institutions involved in diagnosing and treatment of patients. We will look at one such project, called the Elin project, which aimed at establishing electronic co-operation between the general practitioners (GPs) and other actors in the healthcare sectors, such as hospitals, pharmacies, and welfare authorities.

The aim of the project was first to develop comprehensive requirements specifications as a basis for user friendly, standardized solutions for electronic healthcare-related communications for GPs. The main aim was "better communication and collaboration, and not just development of technical solutions for message exchange." This included the development of solutions for exchange of admission and discharge letters, laboratory orders and reports, illness and doctor's declarations, prescriptions, and communication with patients. The project had a strong focus on standards representing the main information objects, like laboratory orders and reports, admission and discharge letters, and prescriptions.

The project was split into three phases. In the first, the focus was on exchange of discharge letters between GPs and hospital departments and outpatient clinics. In the second phase, the focus was on exchange of discharge letters between medical specialists' offices and GPs, exchange of orders and reports between radiology laboratories to GPs, and information exchange with patients. The third phase focused on improving and piloting the technical solutions. The II's architecture was derived from what we can call the "EDI paradigm." That means that the overall II would be built by adding functionality to the applications the users were using, like the GPs' patient record systems for sending and receiving the specified messages. This means that all vendors of applications within the use area need to be involved and agree on the specifications and implementing them.

A number of challenges surfaced. For example, the existing EDIFACT standards did not fit well with the defined requirements, and for some messages, standards were not yet available. Another challenge was that the exchange of the messages took too long time for various (and often mysterious) reasons. Accordingly, new standards and messages had to be specified based on a web services model but within the framework of the EDI paradigm and its architecture.

The project has played a major role in the development of user requirement for ICT solutions supporting communication between GPs and other healthcare institutions, which are well aligned with user

needs and requirements from healthcare authorities. The project also specified a standardized architecture for solutions for information exchange between GPs and hospitals (Aksnes 2006). It was quite successful in establishing strong, enthusiastic collaborative networks of users and suppliers. However, the implementation and diffusion of solutions have definitively been very, very slow. In spite of this, the approach taken by the Elin project has been considered a great leap forward compared to previous efforts within the same domain because it had a stronger focus on user requirements and less on specification of technical standards only. For this reason, it triggered a series of follow-up projects in related areas. But the success of these projects in terms of developing solutions that are adopted by the intended users is modest.

30.4.2.2 Case Analysis

The overall approach taken by the Elin projects is similar to Medakis, and so are the outcomes. But there are also differences. The overall complexity of the work practices one aimed at supporting is significantly lower. But the most important difference is the complexity of the organization developing the Elin IIs, that is, the overall complexity of the actor-network created by the chosen architecture. The organization of the development work was a direct side effect of the choice of architecture.

Even though the number of people involved was rather small, the project involved many different and totally independent vendor organizations. The way the development work was organized was a direct implication of the architecture chosen, that is, the EDI model where the information exchange is implemented as add-ons to and tightly integrated with the applications in use. This work can hardly be done by others that the applications vendors. So all of them needed to be involved, they had to agree upon quite complicated technical specifications, and each of them needed to implement the specifications “correctly.” The experience is that this requires tight coordination between a large number of independent actors—in fact, tighter coordination that what is possible.

30.4.3 Telemedicine in Ambulances

30.4.3.1 Case Presentation

The last case is the implementation of a telemedicine solution in ambulances. This is a successful case—largely due to the bootstrapping strategy followed (Hanseth and Aanestad 2003).

Østfold is the south-easternmost county in Norway, with a population of around 250,000 on an area of 3600 km^2. Until January 1, 1998, there were five independent public hospitals in the county, each with their own fully equipped emergency care unit (ECU). In a process of rationalization and centralization, the hospitals were merged into one organization. The number of ECUs was reduced to two, which created public concern over increased transport time and possible loss of lives in emergency situations. Also time spent within the hospital before treatment is started (“door-to-needle-time”) is generally longer in large than in small hospitals. For example, for myocardial infarction, treatment should preferably be given within an hour (“the golden hour”). Usually myocardial infarction is treated with thrombolytic agents that dissolve the blood clots; however, this should not be given in certain cases as it may cause massive bleedings. The procedure was thus to wait with thrombolytic agents until the patient was brought form the ECUs to the heart intensive care unit and a doctor had verified the diagnosis of myocardial infarction using electrocardiography (ECG) equipment. This means that in many cases the patients do not reach doctors that can give this important treatment within an hour—unfortunately with serious consequences.

In 1996, prior to the merger, one doctor had heard of MobiMed, a telemedicine systems that facilitated transmission of text and ECGs from ambulances to a receiver (e.g., in a hospital). He and some ambulance drivers went to look at the system in use in Sweden. When approaching the county’s health administration, the doctor did not manage to convince them to support this financially, but he got a permission to try out the system. The vendor lent the equipment, and in February 1998, two senders were

installed in two ambulances, and a receiver was installed in the cardiology ward in the hospital where these ambulances would bring their patients. The first aim was to transmit ECG to the cardiology ward for interpretation by a doctor. A verified diagnosis of myocardial infarction would allow the ambulance personnel to bypass the ECU and bring the patient directly to the heart ICU.

The ambulances in this town were selected because there was here a rather high likelihood that there would be an anesthesia nurse available for emergency trips. Anesthesia nurses were trained in using the equipment, and the practical testing started. During 1998, it was used on 166 patients; of these, 16 had an infarction. In these cases, the ECU was bypassed and the "door-to-needle time" was reduced between 25 and 30 min. The ambulance personnel were also taught how to use an ECG recorder, and they practiced on each other during quiet time periods. After some time, they were also allowed to use the equipment when there were no nurses in the ambulances.

In January 1999, the ambulance nurses were allowed to administer the thrombolytic medication (i.e., giving the patient the shot) after the diagnosis was verified by the doctor on duty at the hospital, and the total time from the patient became ill to the medication was given ("call-to-needle-time") was further reduced by 25–30 min. Sometime later the ambulance personnel were also trained and allowed to administer the medication.

Based on the success with the first two ambulances and the benefits and savings that they could demonstrate, the county's health authorities decided to support the purchase of the equipment also for ambulances from the other towns that did not have an ECU. Here, the equipment was installed in April 2000, and the transition from just bypassing the ECU to also give medication in the car came about in just 6 months (October 2000), as compared to about 1 year in the first case.

During 1999, the Norwegian health authorities were approving the practice where nurses were administering the medication after a verified diagnosis. Up to that time, they could do it as a task delegated by the doctor setting the diagnosis. Such an approval from the authorities was necessary to scale up the activities. Later on, a similar authorization was given to the ambulance personnel and how to do it was included into their regular education.

By December 2001, it was decided to purchase senders also for the rest of the ambulances, including the towns *with* an ECU. The aim was then not to administer medication in the ambulance but to bypass the ECU when appropriate. Similar projects were started in several other counties and the extension of the system for also supporting the diagnosis of brain stroke was under discussion.

30.4.3.2 Case Analysis

This case demonstrates, first of all, that substantial benefits may be obtained with limited resources when an appropriate strategy is chosen. In the two previous cases, the chosen strategy generated an unmanageable complexity. Like the DIPS case, this one followed a strategy keeping the complexity at lower level. But also this case was complex in the sense that it included a rather complex mix (actor-network) of technological, medical, and legal issues. First of all, this case demonstrates the importance of an evolutionary and learning centered approach, which balances short-term gains and long-term strategic aims. This evolutionary strategy was crucial in order to prove that it was possible for first nurses and later on other ambulance personnel to give the shots to patients in a safe way. This was achieved within a framework of collaborative arrangements between personnel in the ambulances and cardiologists in the hospital that were developed over time in combination with the overall II that was established. These collaborative arrangements were developed in tandem with new rules and regulations that made these arrangements legal at the same time as they both (regulations and collaborative arrangements) were based on solid practical experience proving them safe.

The evolutionary process strategy chosen was made possible by key features of the technological architecture: a very simple technological solution, which was loosely coupled to the larger infrastructure in terms of the existing equipment in the ambulances and the EPR solution and overall IT infrastructure in the hospitals. Lastly, the strategy was also supported by the entrepreneurial governance regime:

The II evolution was primarily driven by a few enthusiastic doctors. This lean governance regime also contributed to making the smooth evolution of the II possible.

30.5 Conclusion

Overall the complexity of ICT solutions, individually and through integration with others, has reached a level of complexity that demands radically new approaches to the way we develop and manage them. Such new approaches also need to be built on new concepts. In this chapter, the concept of IIs is used in order to capture the complexities ICT developers and managers are confronted with, the key characteristics of these complexities, and the challenges they raise regarding their development and management. The chapter also points to some ways of coping with these challenges.

The key characteristic of IIs is, of course, their complexity. Complex systems are evolving in a way largely driven by side effects. So managing IIs needs to focus on these side effects—how to avoid creating them but at the same time draw upon them. In addition to their complexities, the key characteristic of IIs is the fact that they are not designed from scratch and that they do not have a life cycle—they just evolve. So approaches to coping with their complexities need to focus on how to shape their evolution—*cultivating the installed base*. In this chapter, three "tools" are presented, which may help us in managing complex IIs: process strategies, architectures, and governance regimes. Managing IIs, then, requires the choice of an appropriate combination of these tools. We have illustrated how some such combinations shape the evolution of three IIs within the healthcare sector. But we have still a long way to go before we have the "toolbox" required for proper management of IIs. Unfortunately, we might never reach that stage because as we are developing better "tools," the complexity—and the challenges for management—is growing. Substantial research into this critical issue is desperately needed. In my view, what is most in demand is research on how specific combinations of the management "tools" mentioned here in interaction shape the evolution of IIs. Based on such research, better advice can be given on how specific "tools" should be selected for specific IIs.

Impact of Culture on Information Systems Design and Use: A Focus on E-Business

Dianne Cyr
Simon Fraser University

31.1 Introduction

For many years, the impact of culture on information systems (IS) design and use has been recognized. Based on cross-cultural research, Ein-Dor et al. (1993) assess that IS are influenced by socio-psychological, demographic, and economic factors. The various factors are integrated into a research framework in which the most important finding is that culture has the potential to impact technical and procedural elements of IS greatly. Accordingly, there are numerous authors who suggest that a viable agenda for research links prior literature on international business and IS (Deans and Ricks, 1993; Niederman et al., 2012; Sagi et al., 2004).

A recent article by Niederman et al. (2012) is useful for assessing key topics in global information management. Based on a decade of research published in the *Journal of Global Information Management*, the authors designate 11 categories or topics that evolve from their investigation. These topics include: (1) adoption and diffusion of technology; (2) cultural variations; (3) e-commerce; (4) e-government; (5) information technology (IT) in developing countries; (6) IT in multinational firms to facilitate global operations and decision-making; (7) knowledge management; (8) managerial and worker actions, beliefs, and values; (9) national infrastructure; (10) offshoring of IS tasks; and (11) IS support of virtual

teams involving multiple cultures.* While these topics are not exhaustive, they do represent a snapshot of the field as evidenced by research published in a journal exclusively focused on global information management. Niederman et al. further note that there are overlapping concerns of international business and IS and that the relationship between international business thinking and global information management is complex. Each of these 11 topics is expansive and inclusion of them all within the scope of this chapter is not possible. However, extracting from these themes, the following pages are focused on areas designated by Niederman et al. (2012) as most significant and where there is greatest representation of research. These areas include e-commerce (or e-business as the terminology used in this chapter) and culture.

Studies of e-business consider characteristics of consumer use of IS functions and website offerings, user differences across cultures, as well as the impact of website design on e-business use. More specifically, this chapter will emphasize website design as the medium of communication in e-business. For several years, researchers have examined the effectiveness of website design related to culture, and the subsequent impact on user trust and e-loyalty in e-business (Belanche et al., 2012; Cyr, 2008a; Flávian et al., 2006; Sia et al., 2009; Smith et al., 2011). These investigations are a reasonable proxy for the impact of culture on IS design and use more generally. Therefore, this chapter aims to contribute to understanding website design elements, which facilitate e-business success in diverse cultural settings. Since a primary goal of e-business vendors is to solicit trust of online users, this topic is likewise discussed.

The chapter begins with a brief overview of e-business and national culture. This is followed by a discussion and research findings about culture and website design. More specifically, we focus on how elements of information design, navigation design, and visual design are influenced by culture. Since trust is central to e-business, this topic also receives attention in a cross-cultural context. In addition to the focus on research, the chapter covers the impact of culture and website design on practice. The chapter concludes with suggestions for future research challenges and new directions for research.

31.2 The Global E-Business Phenomenon

The rapid increase of Internet users globally is staggering. Equally impressive is the surge in the number of people shopping or searching for product information online. As of December 31, 2011, Internet users are over 2.2 billion strong, which represents 528.1% growth since 2000 (Internet World Stats, 2011). Of these Internet users, the majority reside in Asia (44.8%), followed by Europe (22.1%), North America (12.0%), Latin America/Caribbean (10.4%), Africa (6.2%), the Middle East (3.4%), and Oceania/Australia (1.1%). Remarkable statistics are the increase in penetration and growth in certain regions. For instance, in Africa the growth of Internet users is 2988% and in the Middle East growth is 2244% in the period from 2000 to 2011. The relative number of Internet users in North America is declining as the number of users in other geographical locations grows.

In 2008, over 875 million consumers had shopped online, up 40% from 2006. Among users with Internet access utilized for shopping, the highest percentage of online shoppers is found in South Korea (99%), United Kingdom (97%), Germany (97%), Japan (97%), and the United States (94%). The most popular and purchased items are: books (41%), clothing/accessories/shoes (36%), videos/DVDs/games (24%), airline tickets (24%), and electronic equipment (23%) (Multilingual Search, 2008). Based on *Internet Retailer*'s 2011 Top 500 Guide, one trend is evident—web-only merchants took business away from the rest of the market in 2010. Combined revenue for 87 merchants indicated that annual web sales increased 32.9% to $46.53 billion in 2010 from $35 billion in 2009. In comparison, according to the National Retail Federation, total retail sales grew year over year about 3% to $2.4 trillion in 2010 from $2.33 trillion in 2009 (Internet Retailer, 2011).

Finally, it was reported earlier that the largest segment of Internet users reside in Asia. With respect to global e-business, China is by far the world's largest online market. A September 2011 study of online

* For an elaboration of each of these topics, as well as observed relationships between them, please see Niederman et al. (2012).

buyers conducted by PricewaterhouseCoopers determined that 86% of China's nearly 200 million online shoppers consider themselves as experts in online shopping. This is compared to 72% of online shoppers in the United States and 70% in the United Kingdom. Chinese shoppers make 8.4 purchases online per month, compared to 5.2 purchases in the United States, or 2.4 in France and the Netherlands (Multilingual Search, 2012). There is no question that e-business is a growing global phenomenon, representing unique cultural requirements.

31.3 What Is Culture?

Culture has implications for Internet usage and affects e-commerce trust (Gefen and Heart, 2006; Jarvenpaa et al., 1999), B2C attitudes (Tan et al., 2007), website development (Junglas and Watson, 2004; Sun, 2001), information and communication technology adoption (Erumban and Jong, 2006), and Internet marketing (Tian and Emery, 2002). There are differences in online communication strategies for target markets between Japan, Spain, and the United States (Okayazaki and Rivas, 2002). Further, differences exist between cultures concerning web interface acceptance and preferences for design features (Evers and Day, 1997; Vyncke and Brengman, 2010). Specific to the IS field, there have been calls for research that integrates IS and national culture (Ford et al., 2003; Gefen and Heart, 2006). In the past several years, this call has been heeded by numerous researchers who have examined culture related to website characteristics. For a comprehensive listing of studies in which culture and e-commerce research are investigated, please see Vyncke and Brengman (2010).

Numerous definitions of culture exist, as do multiple levels of culture (Karahanna et al., 2005; McCoy et al., 2005). Within a given national culture, there are individual, team, or organizational differences—but it is expected there will be a dominant set of shared cultural values, attributes, beliefs, and behaviors (Erumban and Jong, 2006; Matsumoto, 1994). Culture is denoted as "a system of values and norms that are shared among a group of people and that when taken together constitute a design for living" (Doney et al., 1998, p. 67). While a single definition of culture is impossible, most frequently researchers have used nation state as a loose categorization for national culture (Doney et al., 1998).

For more than 30 years, researchers have relied on Hofstede's (1980) work to make comparisons based on country affiliation. Hofstede's dimensions of individualism–collectivism, power distance, uncertainty avoidance, or masculinity–femininity have been frequently used in previous research in IS, and more specifically in e-commerce (Vyncke and Brengman, 2010).* Although there have been questions regarding the validity of using Hofstede's findings, results of his work are supported quantitatively and qualitatively by numerous studies in various disciplines (Sondergaard, 1990; Straub, 1994). Researchers often use Hofstede's classifications to study social psychological phenomena (Dawar et al., 1996; Gefen and Heart, 2006; Yamagishi and Yamagishi, 1994), computer self-efficacy (Srite et al., 2008), and specifically cross-cultural differences in an e-business context (Cyr et al., 2009a; Jarvenpaa et al., 1999; Simon, 2001).

In addition to Hofstede, other cultural work related to website design relies on Hall's (1976, 1990) two dimensions of culture for context and time (Smith et al., 2013 Vyncke and Brengman, 2010). Regarding context, Hall contends that meaning is formed based on how information is perceived, and that the form and function of information varies between cultures. Certain high context cultures like Japan rely on implicit information embedded in a context of social cues such as body language, eye movement, silence, or other nuances. Alternately, in low context cultures such as Canada, there is reliance on explicit forms of communication as found in text or speech. In addition, Hall categorizes cultures based on how members of that culture manage and perceive time. In monochronic cultures like Canada, time is seen as linear and in fixed segments that can be quantified and measured. Members of monochronic

* It expected most readers are familiar with Hofstede's categorizations so they will not be elaborated here. However, for a thorough review and comprehensive discussion of cultural theories (including Hofstede's work), as well as culture related to IT, the reader is referred to Corbitt et al. (2004).

societies tend to focus on a single task within a specified period of time and work on it until completion. In polychronic societies, time is viewed as continuous and unstructured, and the completion of the task is more important then the schedule of achieving it. Latin countries are examples of polychronic cultures when time is flexible.

In addition to an examination of users who differ by country, a useful but less utilized approach is to investigate differences and similarities between countries based on Clustering Theory (Hartigan, 1975). According to Clustering Theory, prediction occurs in two ways. First, if a group (country) is classified into a given cluster (country cluster), then information about behaviors or values of other members of that cluster would serve as predictors of expected behavior of the classified group. Second, measures (such as website design elements) that demonstrate a cultural affinity would be predictive of other members of another given group as long as they belong to the same cluster. For example, user perceptions of website design in Canada would be aligned to the United States since users are within the same cultural cluster. This approach is consistent with cultural researchers (i.e., Ronen and Shenkar, 1985) who adhere to a "culture cluster" model.

An alternate perspective concerning IT use does not focus on the impact of culture, but rather that IT and knowledge management systems may have a suppression effect (Mason, 2003). In this case, technology has a homogenizing effect on national preferences, including IT design and use. However, based on the majority of work related to website design in e-business, culture does matter (Cyr and Trevor-Smith, 2004; Smith et al., 2011). As an additional caveat, while research has mostly focused on culture and IT, an emerging and interesting avenue of consideration is how *socio-cultural* perspectives have a role to play in how users think about and utilize technology. More specifically, Cyr et al. (2009b) examined how socio-cultural values of masculinity and femininity were expressed not only across different cultural groups but also between men and women. The findings of this study will be elaborated in a later section of this chapter.

In sum, culture is pervasive and influences how users perceive ITs. Culture has an impact on the design and use of technology, and in this chapter, the spotlight is on website design. In the following sections, key elements of website design in an e-business context are elaborated, together with the impact of culture on the design–use relationship.

31.4 Culture and Website Design

Online consumers are attracted and engaged by effective website design (Agarwal and Venkatesh, 2002; Cyr, 2008a; Fogg and Tseng, 1999; Fogg et al., 2002; Hoffman et al., 1999; Nielsen, 2001). According to Gommans et al. (2001, p. 51), "A website has to be designed for a targeted customer segment … Local adaptation should be based on a complete understanding of a customer group's culture." The merging of culture and usability is known as "culturability"—when cultural elements in website design are expected to affect the way a user interacts with the site directly (Barber and Badre, 2001). When websites are culturally appropriate, or "localized," then users are more likely to visit them, spend time on the site, and to revisit them in the future (Barber and Badre, 2001; Evers and Day, 1997). Localization is the process of adapting a product or service to a particular language, culture, and desired local "look and feel." In localizing a product, in addition to language translation, details such as currency, color sensitivities, product or service names, images, gender roles, and geographic examples are considered.

Many corporations with international operations operate multiple country websites, and many of these websites are designed to exhibit localized characteristics. For example, in April 2012, Coca-Cola operated 157 websites for different countries. This is an increase of 32 websites from June 2009 (as reported in Vyncke and Brengman, 2010). Related to the earlier discussion of Internet usage and e-business, Coca-Cola segments its markets into six geographical regions with multiple websites in each: North America (4), Latin America (22), Europe (35), Eurasia (32), Africa (52), and Asia Pacific (12). Recall that some of the highest growth of Internet use was in Africa, with 2988% increase from 2000 to 2011.

It is interesting to note that Coca-Cola has 52 websites for Africa. In the North American market, two websites exist for the United States (English and Spanish) and two more for Canada (French and English). For the American sites, besides language, there are multiple other differences including use of color, design features such as animation, navigation, and type of information provided. These design differences, therefore, localize the website and make the site more appealing to local users.

Further, based on research investigations, different user preferences are found when design characteristics are considered across cultures (Cyr et al., 2009a; del Galdo and Nielsen, 1996; Marcus and Gould, 2000). In a study that systematically compared domestic and Chinese websites for 40 American-based companies, significant differences in cultural characteristics were found for all major categories tested (Singh et al., 2003). Cyr and Trevor-Smith (2004) examined design elements using 30 municipal websites in each of Germany, Japan, and the United States. Use of symbols and graphics, color preferences, site features (links, maps, search functions, and page layout), language, and content were examined, and significant differences were uncovered in each design category. In other research in which color (Cyr et al., 2010) or human images (Cyr et al., 2009a) were specifically investigated, cultural differences were likewise noted across culturally diverse groups.

Vyncke and Brengman (2010) aimed to determine if "culturally congruent" websites are more effective than websites when culture is not taken into account. A culturally congruent website is one that is localized (as defined earlier) and therefore matches the norms, values, and expectations of the user. Cultural congruency is measured on a variety of dimensions as identified by Singh and his colleagues (Singh and Baack, 2004; Singh and Boughton, 2005) based on the degree to which a website was localized. Websites range from standardized, when there is no customization across country locations, to highly localized. In the Vyncke and Brengman study, website effectiveness was determined based on whether or not users perceive a website to be useful, easy to use, entertaining, and facilitating positive attitudes and behaviors that result in users wanting to return to the website in the future. In total, 27 research studies published in 16 different journals are evaluated for cultural congruency related to effectiveness. This investigation provides strong empirical support for the positive impact of cultural congruency on performance measures.

31.5 A Suggested Taxonomy of Design Characteristics

Overall, design features have been broad and diffusely defined. However, in the realm of user experience design, Garrett (2003) suggests a number of viable design categorizations including information design, visual design, and navigation design. These categories encompass much of the research conducted in the website design area. They are used and experimentally validated by Cyr and her colleagues over several years from 2004 to 2012. It is expected that information design, visual design, and navigation design provide a useful framework for considering websites generally as well as culturally embedded websites in e-business. These categories are elaborated in the subsequent sections.

Information design refers to website elements that convey accurate or inaccurate information about products or services to a user. "[C]ustomers dissatisfied with web site information contents will leave the site without making a purchase" (McKinney et al., 2002, p. 308). Information is considered an important prerequisite to trust (Flavián et al., 2006; Yoon, 2002). Furthermore, there are differences in the type and amount of information that is considered appropriate across cultures. In North America, substantial amounts of product information are considered desirable, while in other cultures, the same level of information would be considered inappropriate as outlined in the subsequent sections (Cyr, 2002, p. 172).

> [O]n the [customer] support side, there's a lot of pride in some European countries. In France they have a long history of what they're doing, and status comes from the knowledge and expertise acquired. So it's very important to only tell customers information about products which they assume it's reasonable not to have … otherwise, it's like trying to tell them how to do their job.

Research comparing user preferences for perceived access and presentation of product information in Canada, the United States, Germany, and Japan uncovered few significant differences between the United States, Canada, and Germany but significant differences ($p < 0.01$) between these countries and highly collectivist Japan (Cyr et al., 2005). Based on qualitative comments from the study, there appears a desire on the part of Canadians, Americans, and Germans for utility—at least as far as obtaining site information is concerned. As one Canadian user elaborates:

> For a first glance I like the first ten bullet points, the ten most important things. But if I'm looking for detail information I want it to be there. For example, the sizes and dimensions or something like that (Ibid, p. 41).

Elements of *Visual design* deal with balance, emotional appeal, aesthetics, and uniformity of the website overall graphical look. This includes colors, photographs, shapes, or font type (Garrett, 2003). Users from collectivist cultures such as China have a strong preference for visuals, whereas users from more individualistic cultures like Germany prefer a logical and structured page layout (Szymanski and Hise, 2000). As an example, in a study by Cyr et al. (2005), which includes Japanese participants and their perception of various website elements, these users noted they preferred pictures, bright colors, and animation. This sentiment is captured by a Japanese user who notes: "I say … use more pictures, more drawings to appeal to Japanese people … Japanese people like the emotional approach" (Ibid, p. XX). Alternately, an American respondent indicates: "… Banners drive me crazy, they are very distracting actually, when I got deeper into the site, there was a flashy thing over here, it is very distracting" (Ibid, p. 41). Color is a common differentiator by culture and connotes different meaning (Barber and Badre, 2001; Singh et al., 2003). Red means happiness in China but danger in the United States.

Navigation design refers to the navigational scheme used to help or hinder users as they access different sections of a website (DeWulf et al., 2006; Garrett, 2003). "No matter how thorough the information content of a site is, a customer who has difficulty in searching and getting the needed information is likely to leave the site" (McKinney et al., 2002, p. 308). User preferences for the form of navigational scheme are expected to vary by culture (Marcus and Gould, 2000). Germans who are moderately high on uncertainty avoidance "feel anxiety about uncertain or unknown matters" (Marcus and Gould, 2000, p. 39), and therefore prefer "navigation schemes intended to prevent users from becoming lost" (Ibid, p. 41). Simon (2001) found that individualistic Europeans and North Americans prefer navigation that enhances movement and makes the site simpler to use. Alternately, Asian/Latin and South Americans (generally collectivists) desire navigation aids to change the appearance of the site without particular concern for movement.

It is known that a website design effective in information design, visual design, and navigation design can support website trust (Cyr, 2008a,b). Further, the comparative degree to which these elements are important to users and engender trust varies across cultures, as further outlined in the subsequent sections.

31.6 Website Trust and Culture

Whether or not a website is trustworthy is an important consideration for potential online buyers. Unlike vendor–shopper relationships, as established in traditional retail settings, the primary communication interface between the user and the vendor is an IT artifact—the website. As such, trust is generally more difficult to establish. A lack of trust is one of the most frequently cited reasons for consumers not purchasing from Internet vendors (Grabner-Krauter and Kaluscha, 2003).

Corritore et al. (2001) provide a definition of online trust that includes cognitive and emotional elements. Hence, trust encompasses "an attitude of confident expectation in an online situation or risk that one's vulnerabilities will not be exploited" (Ibid, p. 740). Website trust implies consumer confidence in a website and "willingness to rely on the seller and take actions in circumstances where such action makes the consumer vulnerable to the seller" (Jarvenpaa et al., 1999, p. 4). Establishing consumer trust in the

website is fundamental to online loyalty, which includes user intentions to revisit an online vendor or to buy from it in the future (Cyr, 2008b; Flavián et al., 2006; Gefen, 2000; Yoon, 2002).*

Trust is a highly researched topic in e-business. Antecedents to website trust vary and include website design characteristics (Cyr, 2008b; Cyr et al., 2009a; Ou and Sia, 2010). Other factors that engender trust are social presence (Cyr et al., 2007; Gefen et al., 2003; Hassanein et al., 2009); perceived vendor reputation (Jarvenpaa et al., 1999; Koufaris, 2002); clear and trustworthy privacy policies (Reichheld and Schefter, 2000); online transaction security (Palmer et al., 2000); and information privacy (Hoffman and Novak, 1996), among others.

Cultural differences prevail related to user propensity to trust. For instance, individualists are more optimistic than collectivists concerning benevolence from strangers (Inglehart et al., 1998; Yamagishi and Yamagishi, 1994). Further, Kim and Son (1998) measured levels of distrust between highly individualist Americans and highly collectivist Koreans and find that 59% of Americans trust members of a different ethnic group in their society, and 57% trust people from a different country. For Koreans, the average responses are 23% and 18%, respectively. According to Yamagishi and Yamagishi (1994), exchange relationships outside a cultural group only occur when there are substantial institutional safeguards such as strong cultural norms or legal sanctions.

Prior research on website trust and culture compared Internet trust in collectivist and individualist cultures (Jarvenpaa et al., 1999). The researchers expect that consumers from individualist cultures would exhibit higher trust levels in an Internet store than consumers from collectivist cultures. Contrary to this hypothesis, no strong cultural effects are found for trust. Alternately, Simon (2001) finds that for information provided on American and European websites, Asians are most trusting (83% positive), while Europeans (46% positive) and North Americans (42% positive) exhibit substantially lower levels of trust toward the websites.

In related research, Cyr et al. (2005) conducts a study to investigate whether or not local websites engender higher levels of trust for web users than a foreign website of the same vendor (Samsung in this case). With reference to earlier work by Yamagishi and Yamagishi (1994) and others, it is expected that users from individualistic cultures such as Canada or the United States would be least likely to trust the local website, and most likely to trust the foreign website than moderately individualistic German users and collectivist Japanese users. When comparing the level of trust between countries for the *local* website, almost no differences are reported between the Canadians, Americans, and Germans. However, there are large differences between the Japanese with Americans, Canadians, or Germans. Contrary to expectations, Japanese respondents trust their local website least, while Germans trust their local site most. Similar results are found for users viewing the *foreign* version of the website.

Closely related to trust and information design is how legitimacy of the vendor, products, or services is conveyed to website visitors. According to Chen and Dhillon (2003), "Since transactions [on the Internet] occur without personal contact, consumers are generally concerned with legitimacy of the vendor and authenticity of products or services" (p. 1). In a study of website users in the United States, Canada, Germany, and Japan, all country groups score highly regarding the need to trust an Internet store with a well-known reputation, and regarding concern for the legitimacy of the online sales contact. As expected, Japanese are most concerned with online risk and security when buying on the Internet (Cyr, 2011). Canadians note they are aware of security problems when using the Internet, but feel the benefits outweigh the risks. As one Canadian describes,

> You realize that some of the concerns the market has, or some of the perception that people have with security are unfounded … The likelihood that someone is going to intercept the transmission between your computer and a website, and decipher it, is very low. (Ibid)

* A thorough review of trust in offline and online settings is not feasible within the scope of this chapter. However, the reader may wish to refer to Rousseau et al. (1998) for a critique of offline trust and Gefen et al. (2003) for a summary of online trust. Also of interest may be how trust differs from distrust in website design (Ou and Sia, 2010).

In research by Cyr (2008a,b), information design, visual design, and navigation design are modeled to determine if a statistical relationship exists between these design elements and trust. A total of 571 participants located in Canada, Germany, or China completed an experimental task and online survey (N = 230 in Canada; 118 in Germany; and 223 in China). Results of the investigation indicate that navigation design results in trust for Canada and China, visual design results in trust for China only, and information design results in trust for Canada only. It is clear there are distinct design proclivities between the countries in this study. Also of interest is that the three design characteristics explain trust better in Canada and China than in Germany. In the case of Germany, it appears that other characteristics not captured in this study also contribute to online trust. This may include the company name and reputation, or perceived security of information.

Hence, while it was already established that affinity to trust varies between cultures, studies that focus on website design characteristics indicate that design elements have the capability to elicit user trust—and that differing design elements are more important in certain cultures than in others.

31.7 Emotion, Website Design, and Culture

Online shopping is recognized to encompass both utilitarian and hedonic components (Childers et al., 2001; Kim et al., 2007; Lim and Cyr, 2009, 2010; Sun and Zhang, 2006; Tractinsky, 2004). Utilitarian-focused shopping is aimed to achieve predetermined and cognitively oriented goals. In terms of website design, effective information design or navigation design assists the online shopper to achieve such goals. On both a theoretical and a practical level, utilitarian outcomes of online shopping are expected to result in perceived usefulness or effectiveness as extensively investigated in IS using the technology acceptance model (TAM) (Davis, 1989).

Alternately, much less researched are hedonic website elements used to create an experience for the online consumer which is positive, enjoyable, and that provides emotive and sensory pleasure (Bruner and Kumar, 2003; Cyr et al., 2006; Kim et al., 2007; van der Heijden, 2003). Recently, researchers examine how vividness (i.e., the richness and in media and information presented to users) influences user emotional responses in e-commerce (Sheng and Joginapelly, 2012). In other work, website "socialness" leads to enjoyment and influenced user intentions to use online products (Wakefield et al., 2011). Finally, the effective use of images or colors on a website can contribute to emotional appeal for users (Garrett, 2003; Rosen and Purinton, 2004).

Further, in the context of hedonic consumer interactions, researchers investigate perceived social presence as an important antecedent to online consumer enjoyment (Cyr et al., 2007; Hassanein and Head, 2007). Social presence implies a psychological connection with the user who perceives the website as "warm," personal, sociable, thus creating a feeling of human contact (Yoo and Alavi, 2001). Hassanein and Head (2007) demonstrate that emotive text and pictures of humans result in higher levels of perceived social presence for websites. As such, social presence straddles the areas of information design and visual design. In addition to social presence resulting in online enjoyment, it has implications for website trust (Cyr et al., 2007; Gefen and Straub, 2003; Hassanein and Head, 2007), website involvement (Kumar and Benbasat, 2002; Witmer et al., 2005), and utilitarian outcomes such as perceived usefulness or effectiveness (Hassanein and Head, 2004, 2006, 2007).

While the foray to investigate hedonic elements of website design is relatively less studied than utilitarian design elements, the amount of research that examines these topics from a cultural perspective is more scarce. Only a few studies have been conducted in which hedonic website design features are systematically modeled across diverse cultures. More recently, research in this area is beginning to emerge. For instance, Tsai et al. (2008) examine emotion and visual information uncertainty for websites using a Taiwanese sample with differing levels of uncertainty avoidance (one of Hofstede's cultural dimensions). Using a three country sample (Canada, Germany, and China), Cyr (2008) discovered that visual design resulted in satisfaction for users in all three countries and trust in China only.

Hassanein et al. (2009) aimed to determine if perceived social presence is culture specific or universal in online shopping settings. These researchers find that for Chinese and Canadian users' social presence led to similar levels of usefulness and enjoyment, but trust only for Canadians. Cyr and her colleagues conducted two separate research investigations with Canadian, German, and Japanese users regarding their reaction to visual design website elements. In one study, survey data indicate that human images universally result in image appeal and perceived social presence; while interviews and eye-tracking data suggested participants from different cultures experience the design images differently (Cyr et al., 2009a). In the second study, website color appeal is found to be a significant determinant of website trust and satisfaction, with differences across cultures (Cyr et al., 2010). Collectively, these research findings highlight unique perceptions and outcomes of users in different countries based on different cultural orientations.

The widely used TAM, which represents utilitarian outcomes for usefulness, ease of use, and behavioral intention (to use the technology) has also received attention in a cultural context (i.e., McCoy et al., 2005; Rose and Straub, 1998; Straub et al., 1997). Although not specific to design elements in an e-business setting, a landmark study by McCoy et al. (2005) examines the viability of TAM with almost 4000 students representing 25 countries. Results of the investigation reveal that TAM is not universal, and in particular does not apply for individuals who are low on uncertainty avoidance, high on power distance, high on masculinity, and high on collectivism.

Further, in a cross-cultural examination of online shopping behavior in Norway, Germany, and the United States (Smith et al., 2013), patterns for cognitive (i.e., utilitarian) and affective (i.e., hedonic) involvement with a website are examined using a TAM framework across the cultures. The key finding is that the TAM model does not apply for Norway and Germany, although it does for the United States where it was developed. Additional findings reveal that as expected, cognitive involvement is an antecedent to perceived usefulness and perceived ease of use in all three countries. However, for affective involvement, there is a relationship to behavioral intention for the U.S. and Norwegian samples, but not for Germans.

In one additional study, Cyr et al. (2009b) uses TAM to examine gender and socio-cultural differences in samples located in Canada and the Netherlands. Canada scores highly on Hofstede's masculinity dimension (i.e., a focus on material success and achievement), while the Netherlands scores very high on the femininity dimension (i.e., a focus on relationships and cooperation). In the study, website design elements are used to create online social presence, which was then modeled to perceived usefulness and behavioral intention (operationalized as e-loyalty). Of particular interest is whether masculinity and femininity impact social presence, perceived ease of use, and trust. Masculinity was further hypothesized to influence perceived usefulness. The results show that while biological sex affects only perceived ease of use, the effects of femininity extend also to trust, and those of masculinity also to trust and social presence. Therefore, masculinity and femininity are relevant predictors in the research model and suggest a need to reexamine the relationship between IS constructs, on the one hand, and biological sex and masculinity or femininity, on the other. Of interest, nationality has a direct effect on masculinity, while femininity is influenced by an interaction of nationality and biological sex. This study further emphasizes the subtle relationships that exist concerning IS design and use across cultures.

31.8 Additional Applications for IS Design and Use

This chapter has been focused on the interplay of culture and IS with a focus on e-business. However, as indicated in the Introduction, there are numerous other related areas in which the lessons learned regarding e-business are also applicable. More specifically, e-business is a technology supported by design characteristics in the realm of information design, visual design, and navigation design. These design elements are likewise relevant for e-government, virtual teams, online corporate training programs, management of IS, or e-health, among other areas.

As one example, for e-government, the same technologies that assist to build trust and loyalty among users are useful as in e-business. Dynamic websites are required that are culturally appropriate, and which engage the user. The main difference for e-government websites is the expectations of the users who view information in the public domain, and who have differing requirements from e-business users. In one study in which trust is evaluated in the e-government tax system of Singapore (Lim et al., 2012), one respondent indicates:

> There is excellent service at the e-file helpline. Also, there are user-friendly fields with help buttons. The entire set up in e-filing is meant to be easy for taxpayers. The system has user-friendly navigation, simple interface, easy for anyone to get tax filing done without adding more grief to the already undesirable task. (Taxpayer)

When design elements meet user expectations and facilitate the completion of online tasks, then trust results. Although the study by Lim et al. does not examine cultural elements, the appropriate use of symbols, colors, etc. for the e-government website in the Singaporean context will contribute to user satisfaction and loyalty. The same can be said for the other topics mentioned above. Further elaboration beyond e-business of design use and applications appears in the sections on practice in the subsequent text.

31.9 Impact on Practice

Website localization carries a substantial cost to companies, particularly those companies which operate in multiple locations (e.g., in 2012 Coca-Cola operated in 157 countries). However, based on much of the research presented in this chapter, effective localization of web content and design features to specific country users is necessary and has the potential to further engender user trust. Despite this finding, many international companies fail to localize their websites.

While in an ideal world, companies will localize their websites for each country or cultural group, it is known that certain countries cluster together regarding user perceptions of website design. For example, users within North American or Latin American clusters are very similar (Cyr, 2013). Adaptation of website design in these clusters may only require minimal modifications. Further, in Canada while language localization (French and English) is essential, other forms of website adaptation are less necessary. It is noteworthy that “cluster localization” serves the purpose of providing some degree of cultural adaptation to user groups, but with a substantial cost savings to online vendors over deep localization procedures.

The importance of creating websites in the local language of the user is obvious, and perceived usability is increased when a website is originally conceived in the native language of the users. Even though translation may be of an excellent quality, there is still a level of cultural distance, which impacts a user’s evaluation of a website (Nantel and Glaser, 2008). Hence quality of the language is important, along with culturally embedded metaphors of the target group. Subsequently, managers for e-business sites will ideally test the usability of their sites for various international locations with respect to language and redesign them as necessary.

In terms of information design, information quality should be high, with online product information complete, detailed, and trustworthy. Information design is especially important to some users (e.g., Canadians), and it is statistically related to trust. This is a beacon to online vendors to pay special attention to effective presentation of information on the website. Type and amount of information varies by country and should also be tailored to particular users. For example, the majority of users note they prefer few product details when first entering a website, and these details should be easily accessible. Detailed information can be embedded at the next level of the website (Cyr et al., 2005). Generally speaking, users in lower context cultural locations especially desire clarity of information and larger amounts of it.

Visual design preferences likewise vary by culture. For instance, Cyr (2008) find visual design to be especially important to Chinese users. Among this group, high-quality visual design, in turn, resulted in website trust. This was not the case for Canadians and Germans who were included in the same investigation. As such, website designers should pay particular attention to the colors, images, shapes, and overall graphical look of websites for high context, collectivist users who prefer a more "emotional approach." More specifically, brighter colors such as red are preferred, along with animation.

Still in the realm of visual design, based on survey data, users universally prefer websites with images including facial features over human images without facial features, or no human images. Human images result in image appeal and perceived social presence, eventually resulting in website trust (Cyr et al., 2009a). In this same study, interview data reveals different categorizations as to how images are perceived. This includes (1) aesthetics—pleasantness of attractiveness of the website; (2) symbolism—the implied meaning of design elements (i.e., that an image of a man and a little girl are a representation of father and daughter); (3) affective property—emotion eliciting qualities; and (4) functional property—website structure as organized or distracting. Of interest, perceptions of images vary by culture between Canada, Germany, and Japan. For example, in the condition when images include facial features, for Canada these are perceived as aesthetic and affective; for Germany as function, affective, and symbolic; and for Japan as affective and symbolic. While images are expected to be perceived differently across cultures, this work suggests a fine-grained analysis of differences and that images must be carefully chosen to be localized to user preferences. An additional finding from the work by Cyr and her colleagues is that partial human images (i.e., a torso only) generally appear unnatural and unexpected to users and therefore should be avoided.

Color appeal has the potential for emotional impact leading to website trust and satisfaction, and subsequently to online loyalty (Cyr et al., 2010). In this investigation, Canadians have a stronger preference for a grey color scheme for an electronics e-business website compared to Japanese and Germans. Germans prefer a blue color scheme for the same website. Similar to the subtleties that occur when using variations of images for website design, when examining colors across cultures user preferences emerged from interview data. For example, the color blue is universally one of the most popular and trusted colors. The cultural differences are still quite significant: for Canadians, this color elicits a wide range of attributes including being perceived as aesthetic, affective, functional, harmonious, and appropriate. For Germans, blue is perceived as functional, affective, and appropriate. For Japanese, it is affective and functional. In sum, from a practical perspective, website designers need to pay attention to color for specific cultural groups—which in turn results in loyalty wherein users revisit the website in the future.

The third design element that is discussed in this chapter is navigation design. While elements of navigation vary, consistency of page layout and quick access to navigational features are universally desirable. Navigation design is highly related to trust in some countries (e.g., for Canadians and Chinese), which suggests that users from these countries expect websites that are clear and transparent (Cyr, 2008a). Navigation itself has cultural nuances. For instance, Canadians expect utilitarian websites that enhance movement and are easy to use. Generally speaking, cultures high in uncertainty avoidance will prefer clear and detailed platforms for how to navigate a website.

Expanding beyond e-business, it would make sense that information design, visual design, and navigation design be tailored to other areas of website design in various cultural contexts. This may include websites used by virtual teams, e-learning-training sites as used for constituents from diverse cultures, or for cross subsidiary IT management committees. For instance, trust is important for virtual team performance (Edwards and Sridhar, 2005) and for distributed teams (Dinev at al., 2006). Based on the material in this chapter, it is proposed that such trust can be developed through effectively designed and localized websites.

As website design becomes more sophisticated, and with emphasis on hedonic elements and how to develop warm and sociable websites, design features for enhancement of social presence in website design become increasingly of interest. As already noted, social presence relies primarily on human images and emotive text—and as such includes elements of both visual design and information design.

Since social presence typically results in enjoyment, trust (Cyr et al., 2007; Hassanein and Head, 2007), involvement (Kumar and Benbasat, 2002; Witmer et al., 2005), perceived usefulness, and effectiveness (Hassanein and Head, 2004, 2006, 2007), then website designers will do well to incorporate images and emotive text as an important element of design—both within and across cultures. However, usability testing will need to be conducted to determine exactly the best method for how this will occur.

The addition of social presence elements is receiving attention in e-health and shows promise to ensure that users remain on health websites or revisit them in the future. Crutzen et al. (2012) experimentally test the addition of social presence elements on a hepatitis website. While social presence elements are of interest to users, there is no significant difference between website viewing when social presence elements are present versus absent. It appears that for e-health websites, information design is paramount, and that users first require trustworthy information; visual design elements are secondary. However, as the authors point out, personalization is an important strategy for e-health websites. As such, communication is individualized for a user, with the expectation that this will result in a more positive experience (Hawkins et al., 2008). In a similar way, social presence elements on e-health websites may require tailoring or personalization—a technique which is commonly used and found to be effective for the dissemination of information on intervention websites (Krebs et al., 2010). Across cultures, differences are likewise found related to masculine and feminine value orientations in website design, and these differences deserve attention. For instance, in higher masculinity cultures, interface design elements are focused on traditional gender/family/age distinctions; work tasks, roles, and mastery; navigation oriented to exploration and control; attention gained through games and competitions; and graphics, sound, and animation used for utilitarian purposes. Feminine cultures emphasize blurring of gender roles; mutual cooperation, exchange, and support rather than mastery and winning; and attention gained through poetry, visual aesthetics, and appeals to unifying values (Zahedi et al., 2006).

Applying the masculinity–femininity concept to international users, multinational companies that market to a variety of countries might do well to align the values of the designers to the users for whom they are designing. That is, rather than have a team of North American web designers localize websites for all country constituents, designers with values of either masculinity or femininity may be matched to the overarching cultural values present within a country. For North America, more masculine-oriented designers would be appropriate, while in feminine cultures such as the Netherlands, designers with feminine-oriented value systems would be employed.

In sum, there are numerous ways in which websites can be adapted to accommodate the preferences of users in different cultures or country locations. Based on the preceding, in addition to more obvious modifications such as language translation, there are numerous subtleties that exist related to information design, visual design, and navigation design, among other design features. While there is a cost attached for companies who localize websites, I propose that this is a necessary component of doing international online business if online shoppers are to trust the website and be loyal to the vendor in the future. In addition, the same lessons for website design in e-business find application in other areas of IS use and design such as e-government, e-health, virtual teams, or other settings.

31.10 Research Issues

While there have been several rigorous studies in which the impact of website design as an IT medium has been examined in e-business across cultures, there is considerable scope for future research in alignment with practical considerations as outlined in the previous section.

One such research area is to move beyond cultural groups as the defining characteristic for the study of website localization. Although there is merit in using Hofstede (1980) or other cultural theorists to determine broad cultural categorizations, an alternative point of view is to utilize a wider variety of country characteristics as they impact user perceived value of websites for e-business. For instance, in a huge study involving 8886 consumers from 23 countries and 30 websites, Steenkamp and Geyskens (2006) considered country characteristics such as “rule of law” and the regulatory system, national

identity, and individualism as influencing users' perceived value in website design. They found that the effects of privacy/security protection (which would be related to trust) on perceived value is stronger for users in countries with weak regulatory systems. Further, users in countries high on national identity find it of particular importance that there is cultural congruity between themselves and the website—and therefore that website localization occurs. It would be of interest to investigate this further as it applies in e-government. Finally, users from more individualistic countries find pleasure or hedonic outcomes to be essential, along with privacy/security protection, and customization of website design compared to users in collectivist countries.

In this vein, in addition to Hofstede's dimension of uncertainty avoidance, Cyr (2013) uses clustering theory (i.e., wherein countries with similar values and beliefs are clustered together) to determine preferences for website design across cultures.* As already noted, this resulted in some remarkable similarities between certain country groupings such as for North America or Latin America. In this same investigation, country indicators such as Internet connectivity and infrastructure, the digital and legal environment, and consumer and business electronic adoption were used to discuss user reactions to an e-business website. In future research, it is suggested that such additional parameters be used more frequently related to website design and use. Such clustering might be used for the adoption and diffusion of various IS technologies such as adoption of large-scale applications (e.g., ERP systems and Intranet facilities) or in more specific adaptations of training procedures or software development for certain cultural groups. In each case, cultural localization can occur, but for similar cultural clusters rather than on a country specific basis.

The collection of individual-level data is an additional alternative to the use of established cultural categorizations for the study of IT use, and website design more particularly. Collection of individually based or "espoused" user data has been advocated by scholars (i.e., McCoy et al., 2005; Srite and Karahanna, 2006), and has significant advantages to determine culturally specific user values. For example, in Canada there are not only significant value differences for French- or English-speaking users but also for numerous other cultural groups. To elaborate, in Vancouver on the West coast of Canada, there is a predominant Chinese community—and even within this "cultural" group, it is expected there are widely varying cultural values related to whether a user is Chinese born in China or indigenous Chinese born in Canada. Collecting data in this way leads researchers into the area of learning more about socio-cultural value systems, in which more specific values are accessed compared to those represented in established global cultural groupings. As research into cultural values and IT use matures, such fine grained comparisons will be useful—if not imperative. The results of such investigations will be useful for better understanding IS employee values and attitudes, and how IS managers can best facilitate successful implementations and strategies based on cultural proclivities. As one example, it is known that in different countries, MIS project managers perceive projects and risks differently (Choi and Choi, 2003; Peterson and Kim, 2003). Additional research on risk based on socio-cultural values will potentially provide more focused and relevant information than relying on country-based cultural groupings.

Research on the topic of IS design and use, including website design in e-business has typically relied on surveys with single or multiple item scales. However, as measurement techniques expand, there is opportunity to delve into new methods that more deeply and comprehensively attend to what users are experiencing. More specifically, neurophysiological techniques such as functional magnetic resonance imaging (fMRI) have been used for testing reactions to product packaging (Reimann et al., 2010), and there is merit to pursue these alternative methodologies as they inform website design communities. To this end, human images in website design (Cyr et al., 2009a) as well as user reactions to different colors on websites (Cyr et al., 2010) have been measured using eye-tracking equipment to determine exactly where and for how long users look at elements of design. Coupled with interviews to determine why users look where they do, these methods offer a systematic analysis of website elements.

* The results of the GLOBE project appear in a series of papers in the *Journal of World Business* by House et al. (2002).

Most recently, a paper published in the top IS journal, *MIS* Quarterly, by Dimoka et al. (2012) charts a research agenda for the use of neurophysiological tools in IS research. The use of methodologies such as eye-tracking and fMRI are part of an evolving research agenda and are well applicable to study IS design and the cognitive and affective outcomes for users related to their reactions to website design principles. In this regard, Djamasbi (2011) examine online viewing and aesthetic preferences using an eye-tracking device, while Sheng and Joginapelly (2012) explore website atmospherics. These methodologies offer precise insights into why users respond as they do—which in turn serves to develop or elaborate design theory.

With respect to the topics as outlined in this chapter, the realm of emotion and hedonic responses by users to various design features is generally under-researched and thus presents opportunities for additional study. As previously indicated, one particular area of future research concerns the application of personalization through social presence elements in e-health. Further study could also be devoted to social presence in website design across cultures, where to date these appears to be only a very few investigations on this topic (i.e., Cyr et al., 2009b; Hassanein et al., 2009). Finally, the impact of design aesthetics in mobile commerce is a contemporary topic worthy of future investigations. Visual design aesthetics significantly impact perceived usefulness, ease of use, and enjoyment of mobile services (Cyr et al., 2006), although how mobile designs are perceived by diverse cultural users is mostly unknown. With the high usage of mobile devices, it would be interesting to know how cultural users perceive various design characteristics—on both utilitarian and hedonic dimensions.

31.11 Summary

The impact of culture on IS design and use is pervasive and very broad in scope. In this chapter, emphasis has been on website design features in e-business, and in particular information design, visual design, and navigation design. These all have potential to influence user trust toward a website, and all have a varied impact related to culture of the user. From a practical perspective, the impact of website localization (and the attainment of cultural congruity) has the potential to turn web browsers into online purchasers, and the implications for vendor profits are substantial as a result. According to Reichheld and Schefter (2000), an increase in customer retention rates by only 5% can increase profits by 25%–95%. Therefore, the development of loyal customer behavior is a valued goal for managers, marketers, and strategists. Further, from a research perspective, there are numerous topics that merit investigation, and there are novel and interesting methodologies that enable investigators to gain new and deeper insights into how cultural variables impact IS design and use.

Keywords

National culture, information systems design, e-business, website design, localization, information design, visual design, navigation design, and website trust.

32.1 Introduction

The essence of usability as a software development goal is that tools and systems can be designed to facilitate and enhance desirable experiences for their users—ease, transparency, engagement, fun, usefulness, self-efficacy, satisfaction—as well as to mitigate undesirable experiences, such as confusion, frustration, anger, disappointment, lack of confidence, and so forth. Usability is a *nonfunctional* requirement in that it describes the criteria for assessing the quality of a system beyond merely specifying the functions that the system performs, its *functional* requirements.

As a supporting framework for achieving usable systems, the insights, guiding principles, and methods of usability engineering are deceptively simple and straightforward. The first is that ensuring the usability of interactive systems is necessarily a *process*: usability cannot be reduced to fixed laws, scripts, or guidelines. The usability process must be initiated at the beginning of the system development process, and continue throughout and beyond the traditional scope of system development. This is a painfully important insight, because it is far more difficult and costly to manage a process than to follow a rule.

The second principle is that usability can indeed be *engineered*: to a considerable extent, usability can be systematically managed through replicable and teachable methods to meet explicit and measurable objectives (often called usability requirements). Usability can be empirically tracked and iteratively improved throughout the system development process to ensure better outcomes. In other words, usability is not a matter of trial and error in development, followed by empirical checking at the end to see if things worked out.

The third principle is that usability is an *open concept*: conceptions of usability have evolved throughout the past 40 years, and continue to evolve. One obvious reason for this is that the nature of interactive systems has evolved very rapidly. The concepts appropriate to understand and manage the usability of a programming environment in 1977, a PC database in 1987, a website in 1997, or a mobile personal system in 2007 are all quite distinct. But, another reason for the continuing evolution of usability is

that our understanding of usability and our arsenal of usability engineering tools and methods have improved continually. The trajectory of usability through the past four decades is that it has become far more articulated, far more nuanced, and far more comprehensive.

These three principles are obviously interdependent and contingent. Thus, the scope and rate of change in interactive systems is a key factor in the dynamic nature of usability itself, which, in turn, is part of why usability must be managed as a process. It is difficult to see any narrowing or slowing in the evolution of interactive technologies and applications. Change is clearly accelerating.

32.2 Emergence of Usability Engineering

32.2.1 Software Psychology

The concept of usability and the practices of usability engineering began to take shape in the context of 1970s' mainframe/terminals system configurations with line-oriented displays, batch processing for many interactions, and purely textual command-driven interfaces (sometimes with cosmetic menus). Early usability research struggled against two persistent fallacies of system development. The first is the tendency of programmers and designers to assume that their own experiences are valid indicators of what other people will experience in using their software. This seems naively optimistic when stated in the abstract, but it is surprisingly seductive. One still sees it regularly among students in introductory software design classes, but in the 1970s, it was a pervasive attitude among software professionals. The second fallacy is that usability flaws can usually be addressed through adding help and training support to the overall system. In fact, serious usability issues cannot be addressed by help and training. Indeed, designers must always recognize that adding help and training is ipso facto adding complexity to the overall system design.

Throughout the 1970s, usability was investigated as part of a project called "software psychology" (Shneiderman, 1980). This effort tried to confront the fallacies of usability with scientific studies of usability phenomena. Of course, in the 1970s, ordinary people did not use computers, and there were no "users" in the sense we understand that term now. Rather, there were a variety of data processing professionals who designed, implemented, maintained, and used mainframe systems and applications, for the most part, as their full-time jobs. The vision of software psychology was to apply concepts and methods of experimental psychology to better understand the problems of professional programmers, including the then-emerging ranks of application programmers. Three examples of early software psychology contributions are with respect to commands and command languages, design problem solving, and collaborative work; these will be discussed in the following paragraphs.

There are many fairly direct mappings of phenomena from experimental psychology into programming. Thus, especially in the 1970s, programs were long lists of expressions, and command interfaces were long lists of command-function pairs. Psychologists had demonstrated severe limitations of human working memory, including distinctive patterns such as primacy and recency, the tendency in memorizing lists to recall items early and late in the list better than items in the middle of the list. It was also known that people spontaneously impose sophisticated structuring on verbal material. Thus, if a command "down" moved the cursor ahead one record, people automatically assume there will be a command "up" and that it will move the pointer back one record. From this, it could be expected that memory failures, including particular patterns such as primacy and recency, and confusions created by badly designed command languages would be pervasive and debilitating in a text-based computing paradigm. And, indeed they were (e.g., Card et al., 1983; Carroll, 1985; Grudin and Barnard, 1984; Norman, 1988).

The psychology of problem solving had demonstrated that humans often decompose complex problems into subproblems and lose track of the dependencies across a subproblem, that they rely on metaphors and analogies in simplifying complex problems, that they frequently underanalyze problems, that they mistake merely familiar problem elements as being more important elements, and that they rarely optimize solutions (Carroll, 1987; Kahneman and Tversky, 1979; Reitman, 1965; Simon, 1972).

Of course, people are also still the best problem-solving engines we know of, and regularly generate deeply creative insights into complex problems, often "solving" problems that were too complex to even be stated precisely. Technologies can be crafted to address the inherent flaws of human problem solving, for example, representing problem analyses and decompositions in ways that help to expose missing parts (Norman, 1988). Technologies can also strengthen the strengths of human problem solving, for example, suggesting criteria for evaluating metaphors and analogies (Carroll and Kellogg, 1989). The technologies of the 1970s were poorly matched to the characteristics of human problem solvers, and this became more obvious as the decade progressed.

Finally, the psychology of programming identified issues and challenges in the coordination of work in teams. Among the most ambitious software projects of the 1960s was the development of IBM's Operating System 360 (Brooks, 1975). The size and schedule of this project required a large team, and a standard conception of the time was the "man-month," in this case, the work a single programmer could contribute in a month. However, reflections on the project revealed that adding team members did not increase team productivity linearly. Indeed, there was a severe drop in productivity owing to the need for additional team members to spend much more time coordinating their individual efforts. In this case, the analysis of software development experience slightly led the basic psychology of collective effort that is its foundation. But since the 1960s, social psychologists have extensively investigated the issues in optimizing collective efforts (West, 2012).

32.2.2 Early Human–Computer Interaction

Software psychology primarily focused on characterizing usability issues with respect to a scientific foundation of psychological concepts and methods. It was largely descriptive and reflective. In the early 1980s, computing was broadly transformed by the emergence of the personal computer. In the course of only a few years, the problems of professional programmers receded as the focus of research on usability. Software psychology was absorbed into a larger area called Human–Computer Interaction (HCI). HCI expanded the software psychology agenda to be more proactive with respect to new concepts, tools, and methods, including a fundamental rethinking of the software development process. This was good timing; the "waterfall" conceptions of software development had failed even for 1970's conceptions of users and applications. In the 1980s, developers were eagerly seeking new paradigms that could help them design for the growing PC world, where the focus was the user interface and the user. HCI took on this challenge, and through the next decade transformed computer science, establishing what is now taken for granted: software that is not highly usable is just a failed software.

Early HCI embraced three distinctive goals. All three contrast with the goals of software psychology, and all three positioned HCI as a focal area of challenge and change in computing. First, HCI was conceived of as an area in which new science and theory would emerge and develop, not merely as an application area for existing basic knowledge. Initially, HCI was an area of cognitive science, and later it also sought to make fundamental contributions to sociology and anthropology. Second, HCI was conceived of as an area in which new models and techniques for software design and development would emerge and develop, not merely as a project to enrich or improve existing software development models. Third, HCI was conceived of as a technology area in which new user interface software and new applications, new software architectures and tools, and even entirely new types of software would be developed and investigated. Remarkably, all of these goals were achieved in the next couple of decades.

In the area of science and theory, HCI adapted descriptive models from many realms of cognitive and social science, including visual and auditory perception, models of routine cognitive skill, mental models, common ground, distributed cognition, activity theory, social psychology, and sociological studies of work and of community (Carroll, 2003). HCI also was a primary incubator for new theoretical perspectives and technical achievements that have influenced basic sciences, including integrated information processing models (Card et al., 1983), analyses of situated actions (Suchman, 1987), and conceptions of distributed cognition (Hollan et al., 2000), activity (Kaptelinin and Nardi, 2012), and experience

(McCarthy and Wright, 2004). This incredibly varied science base is used in many ways in usability engineering, including design techniques (such as metaphorical design), design and evaluation tools (Bellamy et al., 2011), theoretically grounded design rationales (Carroll and Rosson, 2003), and conceptual frameworks for critiquing designs (McCarthy and Wright, 2004).

In the area of models and techniques for software development, HCI framed the principle of iterative development, the claim that systems can never be successfully specified without extensive prototyping and refinement (Brooks, 1975; Carroll and Rosson, 1985; Gould and Lewis, 1985). The principle of iterative development entrained several further paradigmatic ideas that have shaped the development process for interactive systems. The paradigm of user-centered design requires that system design goals be aligned with the goals of the eventual users of the system. This is sometimes achieved through empirical requirements development, empirical studies of user activities and preferences that are then used to guide envisionment of future systems. Sometimes, it is achieved through direct user participation in the design team, called participatory design.

Iterative, user centered, and participatory design alter the system development process in fundamental ways. These paradigmatic commitments entailed a wide variety of specific usability engineering concepts and techniques to gather data from or about users and to represent and interpret that data. For example, creating scenario descriptions of user activity—essentially stories—is now a core technique in interactive system design, often called scenario-based design (Carroll, 2000; Rosson and Carroll, 2002). As late as in the 1980s, this was seen as a radical approach to software development; today, not doing it would be radical.

In the area of software technology, HCI research produced software architectures and tools that modularized graphical user interfaces and their many successors among personal devices, embedded systems, immersive systems, etc. The initial design strategy was to isolate user interface functionality in a User Interface Management System (UIMS), to make it easier to adjust characteristics of the user interface through the course of design iterations, without entailing disruption to underlying system functionality. Although such a clean separation proved to be intractable, UIMS work helped to establish a software requirement of malleability to enable iterative design.

32.2.3 Managing Experience Design

HCI is inescapably a design discipline, but the term *design* has a variety of different meanings. HCI is a design in the sense that creating interactive systems is always an ill-structured problem; a problem that can only be stated precisely after it is solved (Reitman, 1965). But, interactive systems and applications have expanded into every arena of human activity, and as the richness of user experiences afforded and evoked by interactive systems has expanded, HCI has also become design in the sense that it shapes our interaction with the social and material world, such as consumer product designs, mass media designs, and so forth. Experience design, as it is sometimes called, is now an important focus in HCI and usability engineering (Diller et al., 2005).

This entails a further expansion of what usability and usability engineering are about. The user's experience is no longer just an issue of understanding what is going on well enough to achieve a specific task goal. That conception of usability is still valid, still necessary, but it is no longer sufficient for understanding the user experience. It can be argued that the user experience was always much more complicated than merely easy-to-learn/easy-to-use. As early as the mid-1980s, it was argued that usable systems should be fun to interact with (Carroll and Thomas, 1988). One way to see this is that until the field had developed far enough to effectively and broadly address the simplest conceptions of usability, such as ease of learning and use, the much richer issues that are currently in focus could not get to center stage.

Throughout the past four decades, the concepts and practices of usability engineering have expanded to manage increasingly richer and more nuanced conceptions of usability. The field has been shaped by external factors, a technology context of new devices and networking infrastructures,

new systems, services, and applications, new user interface designs, and new types of users with an ever-widening range of interests and motivations, domain knowledge and knowledge of computing, etc. But it has also been shaped by an astounding diversity of skills and sensitivities among its researchers and practitioners. There is now a solid core of usability engineering tools and practices, as well as an active and rapidly advancing frontier of new concepts and techniques growing year by year.

32.3 Core Methods of Usability Engineering

The tools and practices of usability engineering are often applied within a life cycle framework, for instance, scenario-based usability engineering (Rosson and Carroll, 2002), contextual development (Beyer and Holtzblatt, 1997), or the wheel model (Hartson and Pyla, 2012). The goal of such frameworks is to recommend and demonstrate the use of a variety of techniques at different points, often in a repeated and iterative fashion, through the development of a system.

A high-level summary of how core usability engineering activities might be integrated within a scenario-based development (SBD) life cycle appears in Table 32.1 (the hypothetical example concerns a new e-commerce website). In the SBD framework, scenarios and associated design rationale serve as a central representation that assures a pervasive focus on the task goals and experiences a design team envisions for users. The scenarios also help team members with differing expertise (e.g., social vs. computational science) to establish and maintain common ground as they discuss usability engineering trade-offs. At different points through the cycle, the usability engineering team may use a range of methods, and in some cases the same basic method may be used in support of different usability development goals.

32.3.1 Direct Observation

The most straightforward way to learn about and respond to human needs and preferences is to observe them as they carry out activities that rely on the system or design concept under development. The types of methods and analyses selected for these activities depend on many factors, including the goals of the observational studies, the resources available to the evaluation team, and the nature of the interactive system being developed. Depending on where a team is in the product development life cycle,

TABLE 32.1 Usability Engineering Methods for Phases of Scenario-Based Design

Life Cycle Phase	Examples of Usability Engineering Methods
Problem analysis: Scenarios synthesizing current practices with associated trade-offs	• Contextual inquiry of administrative employees using BuyOnlineNow.com to order office supplies • Convenience survey of current users of amazon.com • Focus groups discussing personas and scenarios synthesized from contextual inquiry and survey
Design: Increasingly detailed scenarios of new activities with associated rationale	• Claims analysis and reasoning about trade-offs in problem scenarios to guide redesign • Participatory design sessions with administrative employees mocking up rough design scenarios for online purchasing tasks
Evaluation: Formative evaluation that guides redesign, complemented by summative evaluation to measure success	• Think-aloud study of administrative employees working with a low-fidelity prototype • Performance study measuring time and errors for several benchmark tasks (e.g., locating item, completing purchase) • Convenience survey of users of a new system once fielded to gather subjective reactions, loyalty, etc.

there may be different evaluation goals in focus (Scriven, 1967). For example, early in the life cycle, *formative* methods are an important mechanism for producing rich and often qualitative findings that can guide iterative design activities. Toward the end of the life cycle, or at critical milestones, the team may instead use *summative* methods to characterize whether and how well usability objectives have been met. In this sense, some of the very early observational studies may include analysis of precursor systems that the target users already employ for similar tasks.

A usability evaluation team may have the luxury of a relatively open-ended mission, spanning many months and having access to a diverse team of usability experts and target users, but more commonly their activities are constrained by time and other resources available. Because of such constraints, the team may need to address their studies to a small set of features or usability questions that imply the use of specific observational methods. For instance, answering a question about two different dialog designs for an e-commerce system implies a performance-oriented observation, perhaps complemented by user satisfaction. In contrast, a more exploratory study of a novel information structure for the same e-commerce site might be best served by a study gathering users' verbal protocols. In the following, we summarize several common observational methods found in usability engineering, ordered roughly by the goals and resources available to the team.

32.3.1.1 Workplace Ethnography

A workplace ethnography would typically be carried out either in the early phases of a project, or perhaps after a project has been completed and fielded. Its goals are to study the established use of some system(s) of interest, without any intervention or structure provided by the observers. In fact, the goal of an ethnographer is to "disappear" into the background of a workplace setting. The primary source of data is the analyst's field notes about what he or she is observing; evaluators may introduce more comprehensive records like audio- or video-recordings, but generally would do so only if these recordings can be made in an unobtrusive fashion. In a pure ethnography, the evaluator would attempt to record everything that is happening, perhaps with a special focus on technology usage episode, but to do this in as unbiased as fashion as possible. Because such evaluations rely entirely on natural work settings and activity rhythms to reveal user tasks or reactions "of interest," they generally require long time periods—weeks or even months—of regular observation. A classic example of workplace ethnography that was used to fuel design thinking can be found in the study of Hughes et al. (1992) of an air traffic control room.

The ethnographic evaluation that is more commonly found in usability engineering contexts is more brief and necessarily more focused in its observation, sometimes referred to as "quick and dirty" or rapid ethnography (Hughes et al., 1995). The general concepts of rich observation and analyst-centered interpretation are still in place, but the abbreviated length and reduced scope assume that an expert observer can enter a situation where design-relevant behavior is underway, and in a relatively short time extract key practices, preferences, and obstacles from workers' behaviors. In the e-commerce example, a quick and dirty ethnographic study may involve observations of shoppers in a store as well as interviews with people who have used existing e-commerce systems; it might also involve the collection and analysis of web interaction logs and context-specific artifacts such as a "filled" online shopping cart, a shopper profile, recommendations made by the system, and so on.

32.3.1.2 Contextual Inquiry

Contextual inquiry provides a more focused approach to field observation; these methods were first described and implemented by Hugh Beyers and Karen Holtzblatt (Beyer and Holtzblatt, 1995) as a centerpiece of their contextual design framework. Like ethnographic methods, this observational technique requires evaluators to collect data from the field as workers engage in their everyday activities. It is particularly useful during the requirements analysis conducted in the early phases of interactive product design, because it produces a number of analysis documents that encode important artifacts currently in use, including technology, physical, social, or organizational factors that impinge on current

practices, and so on. The goals of this technique are similar to rapid ethnography, but the data collection includes more intervention from the observer.

A typical setting for contextual inquiry might include an observer who sits near the workstation or desk of a worker engaged in everyday tasks. The observer watches and takes notes (perhaps also digital recordings), as would an ethnographer. However, the observer's presence is more salient to the worker (e.g., because of proximity) and she is expected to ask questions at times when something of "interest" takes place. This requires the observer to begin the session with a particular focus, perhaps even a set of task-related questions, and to inject these concerns when as relevant. Early on in a system design process, the data collection may be guided by very generic prompts, for example, "Why did you do that?" or "What just happened?" but at times it may be appropriate to make these more specific, for instance, "How did you know it was time to press the Submit button just now?" In our e-commerce example, a contextual inquiry could be directed at either (or both) shoppers in a store setting (e.g., shadowing and observing but also asking shoppers about their search and decision making) or shoppers who interact with an existing e-commerce site.

32.3.1.3 Think Aloud Observations

When usability evaluators want to probe the goals, expectations, and reactions of a user to a particular set of user interface features or controls, they may conduct a session in which they ask users to "think out loud" about their experiences while attempting a task. Such sessions could be done in a field setting (e.g., in conjunction with contextual inquiry visits), but more commonly take place in a laboratory setting where participants are recruited to work with a system while their mental experiences are vocalized and recorded. The resulting auditory file is typically synchronized with a log of their system interactions, and is often termed a verbal protocol (e.g., as in the methods pioneered by cognitive psychologists studying problem solving [Ericsson and Simon, 1980]).

In a typical think aloud session, a representative user will be asked to attempt a specified task (e.g., locate and order *The Girl with the Dragon Tattoo* using Amazon.com), while also saying out loud her moment-to-moment interpretations of what she sees, her plans for what to do next, and her reactions to the system's responses at each step. The evaluator's goal in this is to infer important aspects of the user's *mental model* (Carroll et al., 1987; Payne, 2003), that is, her current knowledge of what an interactive system can do for her and how to instruct it to meet these goals. These results are particularly useful if the software being designed relies on novel or unusual information abstractions (e.g., new vocabulary or conceptual relationships), or if it relies on user interface controls that have not been seen or used in similar systems. These studies are most useful when the primary objective for the system is that it requires little, if any, learning for new users. Because a think-aloud requirement creates a secondary—and often distracting—task with respect to the primary usage task, these methods would normally be used only to serve formative evaluation goals.

32.3.1.4 Human Performance Studies

The most common form of observational study—and what most usability practitioners mean when they talk about doing a user test—is a controlled study of representative users' performance with an interactive system. The method is straightforward: a set of typical tasks is designed to exercise the aspects of a system needing feedback, and users with characteristics similar to those of the project's target users are recruited to carry out these tasks (Card et al., 1983).

For instance, continuing with the e-commerce example, a team might design four to five product search or purchasing tasks that involve different subdialogs within a high-fidelity prototype; perhaps some rely on recommendations or reviews, whereas others are more specific examples of item location or purchase decisions. The data collected in these cases would be objective in form and might include: (1) the number of steps required to complete the task; (2) the actual path followed; (3) the number of missteps taken; (4) the time required to complete the task, and so on. These data would be summarized for comparison to preestablished task performance expectations, perhaps based on competitive analysis,

on pilot studies with an earlier version of this system, or mathematical human performance models. In a formative evaluation setting, such data would likely be complemented by other methods such as those described earlier, but for summative evaluation, they might be used on their own to determine relative success or failure of the system with respect to user performance.

32.3.2 User Expectations and Preferences

Beyond direct observation of behavior, usability engineers normally seek to gain insight into users' expectations, beliefs, or experiences with respect to the system or design concept. One challenge in this process is assuring that test users report their actual feelings as accurately as they are able. There is a general tendency to exhibit socially desirable behavior, and in a system test, this may bias participants to be more positive than their experiences warrant. Another challenge is to evoke reactions that are nuanced and specific, rather than "Sure, I like this!" or "There is no way I would ever use this system!" Finally, usability engineers must be careful to frame users' reports of their expectations and preferences as subjective data that can be affected by a wide variety of individual differences and contextual factors.

32.3.2.1 Focus Groups

Usability engineers may conduct focus group sessions in the early phases of a software development project; group discussions are particularly useful for exploratory data collection. A group of representative users (or perhaps other stakeholders, for instance, decision makers) is gathered together and guided through a discussion about issues relevant to the current phase of system development. Depending on the level of design and development, the discussion may be anchored by demonstration of a design storyboard or even an early prototype. In SBD, scenarios are often communicated informally as textual narratives that revolve around personas (Cooper, 1997), but with a bit more effort, they can be elaborated using sketches or screen shots that capture key aspects of the imagined interaction sequence.

Early on in design, before system functionality or user interactions have been proposed, a focus group may be shown other existing technologies that are related to the design ideas being considered; in our e-commerce example, a session may start out with a few videotapes of people using amazon.com, so as to ground the discussion on particular aspects of current approaches. Depending on the time and resources available, the facilitator may rely instead on a semistructured script of questions or topics. Focus group discussions would normally be recorded for later review; a video of the participants interacting with each other can also be helpful in later analysis of when and how different ideas were generated. A typical result from a focus group would be a summary of ideas raised, perhaps organized by the question or topic that evoked the ideas. If the group has discussed specific design features, there may be a more detailed analysis of the positive and negative comments that were made, or the suggestions for changes.

32.3.2.2 Interviews

An interview is similar to a focus group, but the questions are directed to an individual. As with focus groups, the interview may be more or less structured and may include demonstrations. Typically, the interview is semistructured such that it includes a set of high-level questions but the evaluator is left free to pursue interesting details that come up, or even to engage in an entirely new topic that seems to be a rich source of information from a given participant.

In an interview, a person answers questions individually, so it is important to establish rapport with her quickly so that she feels comfortable enough to expand on her personal experiences and attitudes. One technique for establishing rapport is to begin the questioning with some background discussion about the participant's current work (or leisure, education, etc.) setting. General background information is simple and easy to provide, and has the added advantage of providing participant-specific context that the interviewer can later inject into questions or follow-up probes. For example, in the e-commerce setting, the usability engineers might ask questions about how often and for what sorts of purposes shopping trips are made, as well as what the interviewee most enjoys or finds irritating about shopping

as an activity. Another useful technique when interviewing is to prompt for examples or illustrations of points being made; by asking the participant to remember and describe specific cases, the interviewer can both clarify what a participant is trying to convey and, in general, evoke a richer experiential report.

32.3.2.3 Questionnaires and Surveys

Usability engineers often develop questionnaires or surveys to gather users' expectations or reactions as a complement to open-ended methods. The analysis of qualitative data gathered during direct observation (e.g., in a think aloud study) can be tedious and time-consuming. In contrast, a well-designed survey can gather probe a number of specific user experiences using rating scales or other item types that are simple for users to complete and straightforward to summarize. In fact, usability professionals have adapted the psychometric methods of sociology and psychology to generate and disseminate several validated scales for usability assessment. For example, the QUIS instrument (Questionnaire for User Interface Satisfaction) was developed in the late 1980s as a research project in the HCI lab at the University of Maryland (Chin et al., 1988); QUIS has been validated and refined over the years and is available for licensing to practicing usability engineers (http://lap.umd.edu/quis).

Existing and validated scales are useful in positioning users' general reactions or preferences. However, by their nature, such instruments are conceptualized at a relatively general level. QUIS includes subscales for general usability objectives such as screen design, vocabulary use, and support for learning. However, usability engineers who need to evaluate novel design features (e.g., a small touch screen or natural language input) will need to extend such instruments with items specifically oriented to assess these features. These additional items will be particularly critical in the formative phases of system development, when the design team is deciding which new ideas to pursue and how to refine them.

When used in tandem with direct observation studies, usability engineers typically prepare a brief background survey that is administered before the tasks are attempted; this survey can be used to gather participants' expectations or other preexisting knowledge that may (1) influence how they approach the task; or may (2) change as a result of working with the new system. A posttask survey may repeat some of these items, enabling an analysis of *changes* in users' expectations or preferences, contrasting their responses before and after their usage experience. For example, in the hypothetical e-commerce project that includes a novel interface for finding and reading product reviews, the background survey might ask users about the perceived cost of finding or absorbing product reviews, and compare ratings on this question to the same item presented after the users try out the new approach.

In addition to the development or adaptation of usability-related rating scales, usability questionnaires and surveys often include open-ended questions (e.g., describe the three things you liked the most about the system you just used). As for other qualitative methods, these items are particularly useful early on in the development process when the goal is to develop as rich an understanding as possible of users' experiences. The open-ended items may also be used to probe a participant's baseline comprehension of specific concepts or procedures that are incorporated into the system design. Responses to open-ended questions may be summarized or coded in a fashion similar to transcripts of interviews or focus groups.

Survey methods are also used for requirements gathering in advance of designing a system, or for field-testing of new software after it has been launched. In these cases, considerable effort should be spent in developing and refining a set of questions that addresses the trade-off between information gathering and survey length, simply because in general participants may not be willing to complete a survey that requires more than 10–15 min of their time.

32.3.2.4 Participatory Design

Focus groups, interviews, and surveys can be used to gather preferences or reactions to an existing or proposed interactive system. In these cases, the design team has the responsibility to make sense of the information gathered from users, determining whether and how best to refine the team's current concepts or prototype system. A more direct way of injecting users' preferences or concerns into a design project is to engage them as participants on the design team. Participatory design activities can take

place at specific points in the life cycle (Muller, 2007) or as a long-term evolutionary process (Carroll et al., 2000; Greenbaum and Kyng, 1991). The general concept is similar to a focus group; however, the goal is not to explore concerns and ideas but rather to generate new design concepts, often represented physically using mock-ups of varying levels of fidelity.

In projects that incorporate participatory design, a single set of representative users often meets repeatedly with the design team and collaborates directly on extending or refining the existing analysis or design representations. For example, early on the process they may help to analyze data collected from field studies, such as snippets from videos collected from earlier fieldwork (Chin et al., 1997). Once a problem situation has been analyzed, the group of prospective users may work with the designers to develop or refine user descriptions or task scenarios that envision new or revised activities (Carroll et al., 2000). As the design ideas become more concrete, the users may also help to sketch out user interface displays or interaction sequences (Muller, 1991). Finally, if the software is being constructed in an open and iterative fashion, and if appropriate end user development tools are provided, the user representatives may even operate directly on the software under construction to make changes to a prototype (Costabile et al., 2004).

32.3.3 Analytic Methods

Software projects do not always have the time or resources to recruit and involve representative users or their surrogates in the development process. Alternatively, they may be working within a task domain where detailed performance studies and optimizations are crucial to the success of the project (e.g., safety- or time-critical problem domains). In these situations, a usability engineer may choose to apply analytic methods—techniques that rely on the usability expertise of professionals to identify and manage usability concerns. Like empirical methods, analytic approaches vary in their precision and the corresponding cost of application.

32.3.3.1 Heuristic Evaluation

One class of analytic methods draws from heuristics or high-level guidelines to structure an analyst's review of a design. The interactive software concepts under review might be preliminary (e.g., initial ideas that have been documented through scenarios or storyboards), or it may be a functioning prototype. The heuristics may be a list of best practices that have been summarized across a number of different projects—perhaps within a "family" of interactive applications such as the user interface guidelines used by Apple or Microsoft. They might also be drawn from expert usability practitioners (e.g., http://www.useit.com/papers/heuristic/heuristic_list.html) or HCI researchers (e.g., the guidelines found in Shneiderman et al., 2009). For instance, one common heuristic is to "Speak the user's language," implying a careful focus on the terms and phrasing used by the system's user interface controls and other explanatory text. An analytic evaluation that used this guideline as a heuristic would result in a detailed critique of vocabulary-based issues, perhaps broken down into different segments of the user population. Of course, most such evaluations would be addressing multiple guidelines or heuristics at once, leading to an extensive report at the end of the analysis. Large companies often maintain internal guidelines that address usability issues; depending on the market for the product, one or more national or international standards may also be consulted (see e.g., http://zing.ncsl.nist.gov/iusr/documents/CISU-R-IR7432.pdf). Thus, a professional usability engineer is expected to gain expertise with many forms of standards and guidelines.

The process of applying usability heuristics and guidelines may range from an ongoing background activity (e.g., an e-commerce usability engineer would always be considering issues of web page accessibility by vision-impaired users) to concrete usability inspection episodes. For instance, an expert might conduct a usability inspection of the e-commerce application in our example by receiving a specified set of tasks for product browsing, searching, purchasing, and so on from the design team, and then enacting a careful step-by-step inspection of these tasks in light of the usability heuristics or guidelines provided

by the organization. The inspection might be conducted by an individual expert, by a pair of experts, or by multiple experts conducting inspections independently. The general goal is to provide a report of usability problems that are evoked by the heuristics; the problems are often further classified by severity, the price of addressing the problem, or other company priorities.

32.3.3.2 Design Rationale

The analysis of a designed artifact's design rationale draws from the precepts of ecological science originally pioneered by Gibson (1966, 1979) and Brunswick (1956). Brunswick showed how some of the central perceptual phenomena identified and investigated with line drawings, such as visual illusions, could be explained in terms of the ways that objects align and occlude in the physical world. Gibson showed that perception in movement permits direct recognition of higher-order optical properties such as the expansion pattern one sees in approaching a textured scene or surface. Gibson concluded that real-world perception typically consists of direct recognition of complex properties, which he called "affordances." This contradicted the most fundamental assumption of perceptual psychology, namely, that higher-order properties, such as being an object or being something that can be poured, are inferred on the basis of piecemeal recognition of local features such as contours, edges, and angles. In HCI, the use of design rationale leverages affordances, arguing that a useful analysis for usability is to consider in detail the affordances—or consequences—of an artifact's features for its use in the world. Typically, such analyses produce trade-off descriptions, because almost every system feature, one can imagine, implies a mix of usability pros and cons for different users in different settings.

One approach to developing and maintaining usability design rationale is *claims analysis*, a method used to hypothesize features of an artifact in use (e.g., as illustrated by a usage scenario) that have causal relations with a set of positive and negative consequences for end users (Carroll, 2000; Rosson and Carroll, 2002). Claims analysis was developed to articulate the causal relations inhering in artifacts-as-theory (Carroll and Kellogg, 1989). It has been incorporated as a central reasoning and documentation method in scenario-based design: throughout the evolution of the design scenarios, the design team reasons about the claims, attempting to envision new features that can address the negative consequences hypothesized, while also maintaining or enhancing the positives (Rosson and Carroll, 2002).

Claims development is a form of analytic evaluation. At the same time, the process can set up a structure for claims-based empirical evaluations—this becomes a form of *mediated* usability evaluation that synthesizes analytic and empirical evaluation methods (Carroll and Rosson, 1995; Scriven, 1967). The claims that are created through an analytic process embody hypotheses about what users will expect, attempt, or experience when engaged in a particular activity context (scenario). Such hypotheses can be tested specifically (e.g., in a controlled study that engages users in the relevant activity) or indirectly (e.g., through a generalization process that leads to broader hypotheses that are evaluated through a series of tests).

In the context of claims analysis, design artifacts under construction (assuming some context of use) always have one or more design features in focus; the analysis helps a design team to reflect on and learn from their design discussions and experimentation. Examples of claims analysis as a usability engineering method can be found in case studies of collaborative learning software (Chin, 2004), community networking software and activities (Carroll and Rosson, 2003; 2008), and developmental online communities (Rosson and Carroll, 2013).

32.3.3.3 Cognitive and Computational Models

Another class of analytic methods has its foundations in mathematical models of human information processing (Card et al., 1983). Rather than inspecting a piece of software to identify problematic features, the cognitive modeling approach requires one to build a formal model of the knowledge and procedures needed to complete a task. For example, in the GOMS method, these models require the decomposition of a user interaction task into goals, operators, methods, and selection rules. The cognitive model produced in this fashion can subsequently be translated into a computational model;

performance parameters can be estimated for the model's primitive operations (e.g., pressing a key, moving a mouse, recognizing a word), and the resulting program can be executed to produce performance estimates (Hornoff and Halverson, 2003). Once a model has been created, it can be revised and re-executed to analyze whether specific changes in task design may lead to performance gains. The use of analytic methods at this level of detail is time-consuming, but may be cost-effective when the tasks being optimized are routine behaviors that will be executed hundreds of times per day by thousands of users (Gray et al., 1993; John and Kieras, 1996).

32.3.4 Rapid Prototyping and Iteration

The most direct way to learn about and respond to human needs and preferences is to observe them as they carry out activities related to the system or design concept under development; in other words, to use one or more of the empirical methods described in Sections 32.3.1 and 32.3.2. A key enabler of this approach is to build prototypes for testing, generally with the assumption that these prototypes will be built rapidly and in a way that enables iteration in response to feedback from users or other stakeholders.

As with other usability engineering methods, rapid prototyping can be conducted at differing levels of detail and veridicality with respect to the design vision. For instance, early in a project, one or more prototypes may be created using everyday office supplies such as cardboard, paper, and colored markers. This phase of usability engineering is often referred to as "paper prototyping." Practitioners have documented a range of useful techniques for constructing these low-fidelity prototypes (Snyder, 2003; http://www.paperprototyping.com).

A low-fidelity prototype might be created to represent key display screens or dialog steps, and users can be recruited to respond and "act upon" the design concepts; the problems and successes they have would be noted and used to guide refinement of the underlying concepts and interaction techniques. In a focus group setting, the team might arrive with storyboards or multimedia animations of current design scenarios, presenting these to the group of users for reactions and suggestions. As the design concepts become more stable, the team's software developers will begin to build software prototypes; this may be done in phases using different authoring tools with increasing fidelity, or in an evolutionary fashion where a single system is gradually expanded and refined until it is fully operational.

A number of usability engineering practitioners have debated and studied the impact of prototype fidelity in evaluating users' performance and subjective reactions to a system under development (e.g., Nielsen, 1990; Sauer et al., 2008; Virzi et al., 1996). Many of these studies have shown that low-fidelity prototypes can evoke results from user tests very similar to those carried out with more veridical systems, particularly with respect to detecting and classifying the most severe problems that a team would almost certainly want to address (Sauer and Sonderegger, 2009). Interestingly, users seem to adjust their aesthetic evaluations to some extent when presented with "rough" prototypes, perhaps recognizing that these surrogates should not be judged according to the same criteria (Sauer and Sonderegger, 2009). Practitioners might be expected to prefer lower fidelity methods, when possible, simply because of the reduced cost of creating them and the simplicity of iteration (e.g., redrawing a screen). However, it is clear that when realistic and comprehensive measures of user experience and performance are required, a fully functioning prototype must be provided. This is unlikely to be available until relatively late in the design and development life cycle. Rudd et al. (1996) discuss the practical trade-offs between low versus high fidelity.

32.3.5 Cost-Justifying Usability in Real-World Settings

As was implied in the discussion of analytic methods and the trade-offs in low- versus high-fidelity prototyping, the costs and benefits of doing usability engineering is an important issue in the real-world settings of companies doing software development. At the most extreme, if the target user population will accept and adopt a piece of software that has horrible usability characteristics (i.e., because it fulfills

an essential function not available in any other way), why would a company spend time and money to analyze and support user interaction requirements? Even when it is clear that a product's usability will influence people's decision to buy and use it, how can a company justify an empirical study of its usability when the team's usability inspection can yield a rich number of issues to consider and address? Why build a high-fidelity prototype at all?

Because of such concerns, researchers and practitioners over the years have attempted to weigh the costs and benefits of conducting usability evaluations. Jakob Nielsen pioneered this thread of work with his proposals for "discount usability engineering" and his development of the heuristic evaluation methods (Nielsen, 1994; Nielsen and Molich, 1990). He has provided a number of analyses that contrast different usability engineering methods, estimates for how many test users are needed to discover critical problems, the role of analyst expertise, and so on. Several detailed discussions can be found on the website he maintains as part of his usability consulting business (useit.com). For example, he summarizes the observed usability improvement (as indicated by task time and errors) across the iterative design of four different case studies, estimating that each new version led to an improvement of about 40% in usability (useit.com/iterative_design). However, Nielsen does not provide the corresponding costs of iterating the designs, nor does he consider the variability in improvement one would expect across different design projects and teams.

One of the first practitioners to describe the use of cost–benefit analysis for usability engineering methods was Claire-Marie Karat (1990). Such a calculation depends on first estimating the benefits, for example, the seconds saved by future users who carry out tasks with a piece of software that has been improved through user testing (an average savings of 4 s per e-commerce transaction for a task carried out one time per week by 100 K users can quickly add up to many dollars of saved customer time). These benefits are then compared to the costs of conducting the iterative design: the costs of one or more usability engineers to analyze tasks, develop test materials, recruit users and conduct test sessions, and so on; the cost of the test users' time and associated testing equipment; the cost of responding to the user feedback, and so on. Of course, any such estimation process depends greatly on the assumptions made concerning the usability engineering methods to be used and their effectiveness in guiding redesign. A number of usability cost–benefit analyses developed by Karat and others can be found in the books edited by Bias and Mayhew (1994, 2005).

32.4 Current Challenges for Usability Engineering

Most of the methods for usability engineering emerged during the 1980s and 1990s, as computers became increasingly pervasive and important as personal productivity tools. During that era, the conventional view of a "user test" was a single user sitting at a single computer with single screen, working on a single-threaded task. Such a setting was quite amenable to engineering methods, because it could be structured, observed, and analyzed with considerable precision. However, the variety in interactive software and user interaction settings has increased enormously in the past two decades, creating tremendous challenges for usability engineers. We turn now to a discussion of trends in both technology and usage settings, along with corresponding implications for usability engineers working in these new arenas.

32.4.1 New Technology Contexts for Usability

Users no longer work alone. Increasingly the presumption is that people are connected to others through their technology and that often their day-to-day activities depend on those connections. As computing has become more ubiquitous in our everyday lives, the devices and associated input and output channels that people use for technology interactions have expanded. Finally, user interaction dialogs have become more intelligent, largely as a result of expanding access to large datasets and a concomitant growth in computational power.

32.4.1.1 The Web and Network-Based Systems

The World Wide Web has become a pervasive element of many technology-mediated activities. For some tasks, the web provides critical support for communication with other people or institutions; for others, it is the broad access to information that is most important. Even software that is designed to operate without a network connection will often rely on the web for delivery of regular updates or other maintenance services. As a result, the networked information and services available through the web must be recognized and analyzed when usability engineers are studying whether and how users will interact with a given software system.

A particularly common way for application designers to leverage the web is in user help and information services (Lee and Lee, 2007). While it is possible to package a core set of information with the software itself, a much larger and more dynamic body of information can be provided through the web. Web-based reference information and other documentation can be maintained and expanded in a centralized and convenient fashion as the application is used and evolves, making the help available more extensive. An application's users may also contribute content, perhaps by asking questions that become an index into the help provided, or by answering questions posed by other less-experienced users (Ackerman and Malone, 1990). More broadly, users regularly turn to the web at large for tips or guidance on how to solve a problem, even when the application offers an extensive help system of its own. Surveys of users' preferences for learning about novel technologies often report strong ratings for either asking a colleague or finding an example solution (Rosson et al., 2005; Zang and Rosson, 2009).

One challenge faced by usability engineers is that the web and its services are extremely dynamic and may result in rather different experiences for different users; the dynamic nature of the web also gives designers significantly less control over the user experience. Although the designers of a web application may carefully architect its content, look, and feel, the boundary between the designed application and the rest of the web may still be quite blurred in users' experiences. Considering our e-commerce example, it would be typical for the service to invite comments or reviews from customers, often with little oversight in the details of what and how comments are posted. It is also quite common for Internet applications to include links to other network content or applications, and it is not clear whether and how users integrate across applications when they follow such links.

32.4.1.2 Ubiquitous Computing

The mechanisms through which users interact with software have also expanded in the past two decades. While the most common context for use continues to be interaction with a personal computer using a mouse and keyboard, other options are increasingly common. Computing devices have decreased in size, and wireless connectivity to the Internet is available throughout the world through telephone or Wi-Fi networks.

As the variety in location and activity contexts of use have broadened, so have the options available for interacting with devices. Users who are moving around in the world may find it difficult to look at a small screen or to interact with mouse and keyboard. As a result, technologies that enable voice or touch input are becoming more common (Ishi, 2008; Vertanen and MacKay, 2010). Sensors built into the devices (e.g., a Global Positioning System for tracking location) can also provide useful information to an application that the individual no longer needs to input. However, adding an input channel that is beyond the user's control can raise a new set of usability issues, for example, problems with maintaining user engagement and appropriate awareness of information collected over the external channel (Brown and Laurier, 2012; Leshed et al., 2008). Because ubiquitous use implies interactions with different devices or modalities depending on the context, system support for synchronizing personal data and application preferences across these different contexts has also become critical.

Ubiquitous computing has usability consequences that are similar to that of pervasive network access; that is, it becomes very difficult to predict exactly where, when, and how an application will be activated to carry out a task. Using a mobile application while driving has very different usability requirements

and consequences than using the same functionality in one's home or office (Williamson et al., 2011). Reading from a display that is outside in natural sunlight is a very different perceptual process than reading the same display under normal office lighting. These real-world, constantly changing usage contexts create considerable challenges for lab-based testing; so usability engineers must rely increasingly on fieldwork to evaluate the effectiveness of their designs.

32.4.1.3 Intelligent User Interfaces

A third general trend for interactive computing is the level of intelligence that software contains. With pervasive access to the Internet, an application can access and process a huge volume of data to "assist" a user with a task. This has become commonplace in e-commerce activities, where customer reviews and ratings are omnipresent, and where the bargains, prices, and even the presentation of products may be finely tuned to the person's prior shopping history. Many online retailers provide social recommendations—guesses as to which items a user might find of interest based on the behavior of other users judged to be similar—to guide users' shopping decisions. In this context, usability experts have worried about the types and amounts of information that is being tracked for individual users (Karat and Karat, 2010), even though most users count on these sorts of guidance.

Designers of learning support systems have long been interested in intelligent user interfaces. These include tutors that build and evolve a model of the learner's current knowledge state so that the learning activities and feedback can be carefully matched to the person's needs (London, 1992). But, like online recommendations, systems that adapt to a given user have become pervasive—even an application as commonplace as a web browser will now adapt to users' location and language; personal mail clients "learn" about what is and is not junk mail; and cell phone battery apps adjust to the owner's typical usage rhythms for energy-consuming features over a 24-hour period. Most of these intelligent adaptations are designed to improve usability and are usually easy to turn on and off. It is, however, still an open question whether an end user would be interested and willing to tune the adaptive model to make it even more effective (Kulesza et al., 2012).

Perhaps, the most salient example of intelligent user interfaces is the wide variety of robots that increasingly are being developed for special purpose activities such as cleaning (Marrone et al., 2002), information provision (Lee et al., 2010), or dangerous work environments like war zones or firefighting (Motard et al., 2010). Often, robots are designed as autonomous systems, but enough of them involve human interaction that an entirely new subarea within HCI has developed: human–robot interaction (HRI; see e.g., the Conference on Human–Robot Interaction series at http://humanrobotinteraction.org/category/conference/). Many of the usability issues in HRI are similar to those studied for years in HCI, for example, the impact and relative desirability of anthropomorphism, or the trade-offs in building affective features into a robot whose job is to answer questions. Thus, although robots may seem qualitatively different from an "interactive application," in principle, HRI should follow the same usability life cycle used by other software projects—fieldwork that assesses how a robot might fit into or enhance current practices, prototyping and formative evaluation to envision and build the system, and summative evaluation to assess whether and how it meets stated requirements (Lee et al., 2009).

32.4.2 New Usage Contexts for Usability

In parallel with changing technologies for user interface development, the activity contexts in which computing takes place have changed significantly in the past two decades. Two aspects that are very relevant for usability engineering are the degree of collaboration and multitasking present in many computing activities.

32.4.2.1 Collaborative Computing

Because users are often connected to a network while they engage in computing, there is a collaborative background to their work or play, even when the application does not explicitly support or encourage

interaction with other people—for instance, simply sending a document or image as an attachment through email represents a loosely coupled form of collaborative computing. When examining current practices as part of a design process, the consideration of an activity's social or cultural context has become a prime concern along with the more traditional human factors stemming from users' physical, perceptual, or cognitive capacities (Beyer and Holtzblatt, 1997; Rosson and Carroll, 2002).

When explicitly designing for collaborative use, usability engineers must address a broad range of factors that interact with the nature and types of interaction that will take place among collaborators. For example, an asynchronous collaborative activity that transpires over different locations and times has rather different needs than a synchronous interaction that connects remote collaborators in real time (Neale et al., 2004). The different options for computer-mediated communication bring different affordances for the style and quality of the exchange (Clark and Brennan, 1991), with text-based communication being adequate for simple information sharing but richer audiovisual channels important for collaborations that rely on evaluation and negotiation of options for decision-making (Monk, 2008). To further complicate the issue, users' communication may change over time, as collaborators construct mental representations of one another that can guide and simplify their interactions (Convertino et al., 2011). Beyond the general concern for matching communication channels to collaborators' needs is the more general requirement for helping users to stay aware of what collaborators have been doing, whether in real time or not (Carroll et al., 2006). For software intended to support global collaboration contexts, a special usability challenge is the conflicts that may arise when global teams use a mix of face-to-face (i.e., within a locale) and remote (i.e., across locales) interactions (Ocker et al., 2009).

32.4.2.2 Multitasking

Modern operating systems are designed to support multithreaded activities, allowing users to launch and interact with multiple applications at the same time. In a work setting, this might mean transitioning in and out of a mail client, a document editor, an analysis package, and so on. Sometimes, the decision to transition is initiated by the user, but at other times, a user is "called to attention" by a notification of an application's status change. In general, the presence of multitasking does not raise new requirements for user interface design and usability engineering. Multitasking increases the importance of features that have long been in focus—for example, providing feedback during and after a task or subtask has been completed, and providing status information that conveys whether and how an interrupted task can be resumed (Norman, 1988). When designers support multitasking directly with complementary input and output channels, the situation becomes even more complex, because users must not only be able to track multiple goal–action sequences in parallel, but may also be required to orient to different configurations of displays or input devices for these different task contexts.

There are many usability engineering challenges that ensue from the complications of web-based platforms, pervasive connectivity and collaborative tasks, and the general trend toward greater and greater multitasking and heterogeneity in devices. To some extent, the challenges are simply those of greater complexity. For example, a meaningful reference task for evaluation may involve multiple parallel tasks, a group of users, or tasks that take place over extended periods of time and multiple locations (Neale et al., 2004). However, the new contexts also foreground new usability issues, for example, issues of *privacy* related to the persistent collection, analysis and repurposing of users' personal data or online behavior, and issues of perceptual and motor "transfer" among rather different input and output devices used for the same tasks.

32.4.3 New Concepts and Methods for Usability

Early HCI focused on software systems to support work activity, typically the activity of single users in the workplace. Today, HCI addresses learning and education, leisure, and entertainment; it addresses people individually, in groups, and as mass society. HCI is now about coping with everyday life, citizenship and civic participation, and very much about satisfaction as a consumer. This diversification has evoked new problems in usability engineering, required new concepts and approaches, and has drawn

new people and skills into the field. The fundamental goals however remain the same: to design and refine software systems to meet human needs. This diversification is a natural consequence of growth and success, though it has created microcosms of specialized usability engineering work that are not always well coordinated with one another or with a broader conception. Nevertheless, these initiatives are driving usability engineering forward.

32.4.3.1 Universal Usability

Many of the most important innovations in display technologies or input devices have emerged from user interface design research directed at meeting the needs of people with disabilities. While the interest in accommodating people with special needs—whether with respect to visual, motor behavior, cognitive, or other capacities—has a long history, the resources and scientific interest aimed at these questions increased significantly in the 1990s, at least partly due to significant pieces of national legislation and policies (e.g., the Americans with Disabilities Act of 1990, the Telecommunications Act of 1996) that mandated accommodations in some work settings. The rapidly expanding population of elderly users in the United States has also helped to fuel research interest in these topics, with annual conferences such as *ACM ASSETS* and *ACM Transactions on Accessible Computing* created to enhance visibility of emerging findings and technology innovations.

A focus on universal usability—sometimes also called universal design—often produces findings or solutions that yield better designs for everyone. For example, the continued progress on voice commands helps not only the motor-impaired but also users who are in a hands-busy environment such as driving or working with mechanical equipment (Schütz et al., 2007). Alternate input devices such as joysticks or foot pedals are often integrated into custom HCI settings like games or training simulations (Zon and Roerdink, 2007). The many years of research on systems for text-to-speech translation not only support low-sight individuals (e.g., using screen readers like JAWS) but also is now omnipresent in voice-based telephone dialogs.

32.4.3.2 Interaction Design

As computer technologies have diversified, approaches to usability have broadened to consider the role and impacts of technology in consumer product design, for example, including furniture (Streitz et al., 1998), kitchen and other household tools (Chi et al., 2007), toys (Tomitsch et al., 2006), electronic books and games (Druin et al., 2009), and even clothing and accessories (Cho et al., 2009). Many such efforts fall under the umbrella of interaction design—often abbreviated as IxD—that differs from usability engineering in its pronounced emphasis on creative design thinking. That is, whereas in usability engineering the designers typically expect to begin with a detailed analysis of users' current practices and associated requirements, IxD designers specialize in out-of-the-box imagination and exploration of how things might be without the constraints of the current world (Löwgren, 2008).

In the IxD vision, the aesthetic characteristics of a design concept are of equal importance to its technical or functional elements, and these characteristics are often tied to physical form of the product. For instance, Apple has developed a consistent and successful design aesthetic through its i-devices; people choose to purchase and use these products not just because they satisfy their task needs but because they like the way the objects look and feel. Because of the importance of the overall aesthetic, sketches and other tangible artifacts are significant means for communicating design ideas. Learning to create and elaborate these early design prototypes is an essential skill for IxD professionals (Buxton, 2007).

32.4.3.3 Experience Design

Similar to IxD, the emerging discipline of user experience design (UX) places great value on the subjective experience of people who will be interacting with technology. UX recognizes that this subjective experience is embedded in a complex network of related concerns, for example, the "family" of products associated with a particular offering, how a product's users feel about the company that produces it, how often and by what means the product will be upgraded, its price relative to competitors, and so on (Diller et al., 2005).

The UX design process centers on the mechanisms for engagement. Design representations such as personas (Cooper, 1999; Grudin and Pruitt, 2002) are particularly popular within this design community, because a well-crafted persona offers a means of vividly evoking subjective experiences. Knowing that 32-year-old Jane Pelham loves to watch professional sports on TV, is an avid cook, and is carefully watching her weight may seem incidental to discussions about a new feature for an office product, but this relatively vivid depiction can help the product designers imagine how Jane would react to a design decision involving support for a touch-screen interface (e.g., how might she use it in the living room vs. in the kitchen). In this sense, UX can be seen as a more holistic version of the SBD process overviewed earlier—it relies centrally on representing and reasoning about individual user experiences rather than generic population statistics, but unlike SBD, the process does not entrain any systematic analysis and representation of design trade-offs and rationale.

32.5 Summary and Conclusions

To appropriate Robert Browning, usability engineering is an area of technical endeavor where our reach must necessarily exceed our grasp. New technology infrastructures, new applications, and new human aspirations drive usability engineering practices toward an expanding frontier of new concepts and techniques. Like many topics in computer science and engineering, we are not likely to ever close the book on usability engineering practices.

Why would we want to? Science and technology are most exciting at the frontier. The primary constant in usability engineering through four decades has been a developmental trajectory. Usability engineering has constantly become richer, more broadly applicable, more diverse conceptually and methodologically, and much more effective. The need for this trajectory to continue is unabated, and the prospects for further innovation and growth, driven by both external technological factors and human imagination, remain strong.

Task Analysis and the Design of Functionality

David Kieras
University of Michigan

Keith A. Butler
University of Washington

33.1 Introduction

In *human–computer interaction* (*HCI*), *task analysis* is a family of methods for understanding the user's task thoroughly enough to help design a computer system that will effectively support users in doing the task. By *task* is meant the user's job or goal-driven work activities, what the user is attempting to accomplish; an individual user's task is not just to interact with the computer, but to get a job done. Thus, understanding the user's task involves understanding the user's *task domain* and the user's larger job goals.

By *analysis* is meant a relatively systematic approach to understanding the user's task that goes beyond unaided intuitions or speculations and attempts to document and describe exactly what the task involves. At the level of large military systems and business processes, the analysis can span multiple users, machines, and organizations; this can still be termed task analysis, but other labels, such as business process analysis, tend to be used. A large-scale analysis is necessary to determine the context in which individual users or systems do their work, and a finer-grain analysis is required to determine how the individual users do their work within that larger context.

The design of *functionality* is a stage of the design of computer systems in which the user-accessible functions of the computer system are chosen and specified. The basic thesis of this chapter is that the successful design of functionality requires a task analysis early enough in the system design to enable the developers to create a system that effectively supports the user's task. Thus, the proper goal of the design of functionality is to choose functions that are both *useful* in the user's task and which together with a good *user interface* result in a system that is *usable*, being easy to learn and easy to use. If the scale is expanded to a larger work context, effective design of functionality becomes the design of work processes, deciding what parts of the work are going to be done by humans and what by machines.

The purpose of this chapter is to provide some historical and theoretical background, and beginning "how to" information on how to conduct a task analysis and how to approach the design of functionality.

Although they are closely intertwined, for purposes of exposition, task analysis and the design of functionality are presented in two separate major sections in that order. Each section will start with background principles and then present some specific methods and approaches.

33.2 Task Analysis

33.2.1 Principles

A task analysis presupposes that there already exists some method or approach for carrying out the work, involving some mixture of human activity and possible machine activity. This method may have existed for a long time, or might be a new, even hypothetical, method based on new technology. The goal of the initial task analysis is to describe how the work is currently being done in order to understand how computing may improve it.

33.2.1.1 Role of Task Analysis in Development

33.2.1.1.1 Development of Requirements

This stage of development is emphasized in this chapter. A task analysis should be conducted before developing the system requirements to guide the choice and design of the system functionality; the ultimate, upper boundary of usability of the system is actually determined at this stage. The goal of task analysis at this point is to find out what the user needs to be able to accomplish, and how they will do it, so that the functionality of the system can be designed so that the tasks can be accomplished more easily, with better quality, etc. While some later revision is likely to be required, these critical choices can be made before the system implementation or user interface is designed.

Designers may believe they understand the user's task adequately well without any task analysis. This belief is often not correct; even ordinary tasks are often complex and poorly understood by developers. However, many economically significant systems are intended for expert users, and understanding their tasks is absolutely critical and well beyond normal software developer expertise. For example, a system to assist a petroleum geologist must be based on an understanding of the knowledge and goals of the petroleum geologist. To be useful, such a system will require functions that produce information useful for the geologist; to be usable, the system will have to provide these functions in a way that the frequent and most important activities of the geologist are well supported.

33.2.1.1.2 User Interface Design and Evaluation

Task analysis is also needed during interface design to effectively design and evaluate the user interface. Most applications of task analysis in software projects are focused on user interface design (Diaper and Stanton 2004a). During interface design, valuable usage scenarios can be chosen that are properly representative of user activities. Task analysis results can be used to choose benchmark tasks for user testing that will represent important uses of the system. A task analysis will help identify the portions of the interface that are most important for the user's tasks. Once an interface is designed and is undergoing evaluation, the original task analysis can be revised to specify or document how the task would be done with the proposed interface. This can suggest usability improvements from either modifying the interface or improving the fit of the functionality to the more specific form of the user's task entailed by a proposed interface.

33.2.1.1.3 Follow-Up after Installation

Task analysis can be conducted on fielded or in-place systems to compare systems or identify potential problems or improvements. These results could be used to compare the demands of different systems, identify problems that should be corrected in a new system, or to determine properties of the task that should be preserved in a new system.

33.2.1.2 Contribution of Human Factors

Task analysis was developed in the discipline of *Human Factors*, which has a long history of concern with the design process and how human-centered issues should be incorporated into system design. Task analysis methods have been applied to a broad range of systems, covering handheld radios, radar consoles, whole aircraft, chemical process plant control rooms, and very complex multiperson systems such as a warship combat information center. The breadth of this experience is no accident. Historically, Human Factors is the leading discipline with an extended record of involvement and concern with human-system design, long predating the newer field of HCI. The resulting task-analysis methods have been presented in comprehensive collections of task analysis techniques (Beevis et al. 1992; Diaper and Stanton 2004a; Kirwan and Ainsworth 1992), and it has been an active area of research within Human Factors and allied fields (Annett and Stanton 2000a; Schraagen et al. 2000). One purpose of this chapter is to summarize some of these techniques and concepts.

Precomputer technologies usually had interfaces consisting of fixed physical displays and controls in a spatial arrangement. So, the original forms of task analysis focused on how the operator's task was related to the fixed physical "knobs and dials" interface. However, the user interfaces provided by computer-based systems are potentially much more flexible, resulting in a need for task analysis to identify what display and control functions should be present to support the operator. In other words, the critical step in computer-based system design is the *choice of functionality*. Once the functions are chosen, the constraints of computer interfaces mean that the procedural requirements of the interface are especially prominent; if the functions are well chosen, the procedures that the operator must follow will be simple and consistent. The importance of this combination of task analysis, choice of functionality, and the predominance of the procedural aspects of the interface is the basis for the recommendations provided later in this chapter.

33.2.1.3 Contributions of Human–Computer Interaction

The field of HCI is a relatively new and highly interdisciplinary field and still lacks a consensus on scientific, practical, and philosophical foundations. Consequently, a variety of ideas have been discussed concerning how developers should approach the problem of understanding what a new computer system needs to do for its users. While many original researchers and practitioners in HCI had their roots in Human Factors, several other disciplines have had a strong influence on HCI theory and practice.

There are roughly two groups of these disciplines. The first is ***cognitive psychology***, which is a branch of scientific psychology that is concerned with human cognitive abilities, such as comprehension, problem-solving, and learning. The second is a mixture of ideas from the social sciences, such as social-organizational psychology, ethnography, and anthropology. While the contribution of these disciplines has been important in developing the scientific basis of HCI, they either have little experience with humans in a work context, as is the case with cognitive psychology, or no experience with practical system design problems, as with the social sciences. On the other hand, Human Factors is almost completely oriented toward solving practical design problems in an ad hoc manner, and is generally atheoretic in content. Thus, the disciplines with a broad and theoretical science base lack experience in solving design problems, and the discipline with this practical knowledge lacks a comprehensive scientific foundation.

The current state of task analysis in HCI is thus rather confused (Diaper and Stanton 2004b); there has been a tendency to reinvent task analysis under a variety of guises, as each theoretical approach and practice community presents its own insights about how to understand a work situation and design a system to support it. Apparently, most task analysis methods are tapping into the same underlying ontology and differ mainly in what aspects are represented or emphasized, suggesting that they could be merged them into a single analysis (van Welie et al. 1998), but in the meantime, the most successful ad hoc approaches address a much wider set of requirements than the user interface. Contextual Design (Beyer and Holtzblatt 1998) is a collection of task-analytic techniques and activities, which will lead the developer through the stages of understanding, what users do, what information they need, and what system functions and user interfaces will help them do it better.

33.2.1.3.1 Contributions from Cognitive Psychology

The contribution of cognitive psychology to HCI is both more limited and more successful within its limited scope. Cognitive psychology treats an individual human being as an information processor who is considered to acquire information from the environment, transform it, store it, retrieve it, and act on it. This information-processing approach, also called the computer metaphor, has an obvious application to how humans would interact with computer systems. In a cognitive approach to HCI, the interaction between human and computer is viewed as two interacting information-processing systems with different capabilities, and in which one, the human, has goals to accomplish, and the other, the computer, is an artificial system which should be designed to facilitate the human's efforts. The relevance of cognitive psychology research is that it directly addresses two important aspects of usability: how difficult it is for the human to learn how to interact successfully with the computer, and how long it takes the human to conduct the interaction. The underlying topics of human learning, problem-solving, and skilled behavior have been intensively researched for decades in cognitive psychology.

The systematic application of cognitive psychology research results to HCI was first proposed by Card et al. (1983). Two levels of analysis were presented: the lower-level analysis is the Model Human Processor, a summary of about a century's worth of research on basic human perceptual, cognitive, and motor abilities in the form of an engineering model that could be applied to produce quantitative analysis and prediction of task execution times; the higher-level analysis was the *GOMS model*, which is a description of the *procedural knowledge* involved in doing a task. The acronym GOMS can be explained as follows: The user has Goals that can be accomplished with the system. Operators are the basic actions such as keystrokes performed in the task. Methods are the procedures, consisting of sequences of operators that will accomplish the goals. Selection rules determine which method is appropriate for accomplishing a goal in a specific situation. In the Card et al. formulation, the new user of a computer system will use various problem-solving and learning strategies to figure out how to accomplish tasks using the computer system, and then with additional practice, these results of problem-solving will become GOMS procedures that the user can routinely invoke to accomplish tasks in a smooth, skilled manner. The properties of the procedures will thus govern both the ease of learning and ease of use of the computer system. In the research program stemming from the original proposal, approaches to representing GOMS models based on cognitive psychology theory have been developed and validated empirically, along with the corresponding techniques and computer-based tools for representing, analyzing, and predicting human performance in HCI situations (see John and Kieras 1996a,b for reviews).

The significance of the GOMS model for task analysis is that it provides a way to describe the task procedures in a way that has a theoretically rigorous and empirically validated scientific relationship to human cognition and performance. Space limitations preclude any further presentation of how GOMS can be used to express and evaluate a detailed interface design (see John and Kieras 1996a,b; Kieras 1997, 2004). Later in this chapter, a technique based on GOMS will be used to couple task analysis with the design of functionality.

33.2.2 Best Practices: How to Do a Task Analysis

The basic idea of conducting a task analysis is to understand the user's activity in the context of the whole system, either an existing or a future system. While understanding human activity is the subject of scientific study in psychology and the social sciences, the conditions under which systems must be designed usually preclude the kind of extended and intensive research necessary to document and account for human behavior in a scientific mode. Thus, a task analysis for system design must be rather more informal, and primarily heuristic in flavor compared to scientific research. The task analyst must do his or her best to understand the user's task situation well enough to influence the system design given the limited time and resources available. This does not mean that a task analysis is an easy job; large amounts of detailed information must be collected and interpreted, and experience in task analysis is valuable even in the most structured methodologies (see Annett 2004).

33.2.2.1 Role of Formalized Methods for Task Analysis

Despite the fundamentally informal character of task analysis, many formal and quasiformal systems for task analysis have been proposed and have been widely recommended. Several will be summarized later. It is critical to understand that these systems do not in themselves analyze the task or produce an understanding of the task. Rather, they are ways to structure the task analysis process and notations for representing the results of task analysis. They have the important benefit of helping the analyst observe and think carefully about the user's actual task activity, both specifying what kinds of task information are likely to be useful to analyze, and providing a heuristic test for whether the task has actually been understood. That is, a good test for understanding something is whether one can represent it or document it, and constructing such a representation can be a good approach to trying to understand it. Relatively formal representations of a task further this goal because well-defined representations can be more easily inspected, criticized, and developed with computer-based tools. Furthermore, they can support computer simulations or mathematical analyses to obtain quantitative predictions of task performance. But, it must be understood that such results are no more correct than the original, and informally obtained, task analysis underlying the representation.

33.2.2.2 An Informal Task Analysis Is Better Than None

Most of the task analysis methods to be surveyed require significant time and effort; spending these resources would usually be justified, given the near-certain failure of a system that fails to meet the actual needs of users. However, the current reality of software development is that developers often will not have adequate time and support to conduct a full-fledged task analysis. Under these conditions, what can be recommended? As pointed out by sources such as Gould (1988) and Grudin (1991), perhaps the most serious problem to remedy is that the developers often have no contact with actual users. Thus, if nothing more systematic is possible, the developers should spend some time in informal observation of real users actually doing real work. The developers should observe unobtrusively, but ask for explanation or clarification as needed, perhaps trying to learn the job themselves. They should not, however, make any recommendations, and do not discuss the system design. The goal of this activity is simply to try to gain some experience-based intuitions about the nature of the user's job, and what real users do and why (see Gould 1988 for additional discussion). Such informal, intuition-building contact with users will provide tremendous benefits at relatively little cost. Approaches such as Contextual Design (Beyer and Holzblatt 1998) and the more elaborate methods presented here provide more detail and more systematic documentation, and will permit more careful and exact design and evaluation than casual observation, but some informal observation of users is infinitely better than no attempt at task analysis at all.

33.2.2.3 Collecting Task Data

The data collection methods summarized here are those that have been found to produce useful information about tasks (see Gould 1988; Kirwan and Ainsworth 1992); the task-analytic methods summarized in the next section are approaches that help analysts perform the synthesis and interpretation.

33.2.2.3.1 Observation of User Behavior

In this fundamental family of methods, the analyst observes actual user behavior, usually with minimal intrusion or interference, and describes what has been observed in a thorough, systematic, and documented way.

The setting for the user's activity can be the actual situation (e.g., in the field) or a laboratory simulation of the actual situation. Either all of the user's behavior can be recorded, or it could be sampled periodically to cover more time while reducing the data collection effort. The user's activities can be categorized, counted, and analyzed in various ways. For example, the frequency of different activities can be tabulated, or the total time spent in different activities could be determined. Both such measures contribute valuable information on which task activities are most frequent or time-consuming, and thus

important to address in the system design. Finer grain recording and analysis can provide information on the exact timing and sequence of task activities, which can be important in the detailed design of the interface. Video recording of users supports both very general and very detailed analysis at low cost; consumer-grade equipment is often adequate.

A more intrusive method of observation is to have users "think aloud" about a task while performing it, or to have two users discuss and explain to each other how to do the task while performing it. The verbalization can disrupt normal task performance, but such *verbal protocols* are believed to be a rich source of information about the user's mental processes such as inferences and decision-making. The pitfall for the inexperienced is that the protocols can be extremely labor intensive to analyze, especially if the goal is to reconstruct the user's cognitive processes. The most fruitful path is to transcribe the protocols, isolate segments of content, and attempt to classify them into an informative set of categories.

A final technique in this class is *walkthroughs* and *talkthroughs*, in which the users or designers carry out a task and describe it as they do so. The results are similar to a think-aloud protocol, but with more emphasis on the procedural steps involved. An important feature is that the interface or system need not exist; the users or designers can describe how the task would or should be carried out.

33.2.2.3.2 Critical Incidents and Major Episodes

Instead of attempting to observe or understand the full variety of activity in the task, the analyst chooses incidents or episodes that are especially informative about the task and the system, and attempts to understand what happens in these; this is basically a case-study approach. Often, the critical incidents are accidents, failures, or errors, and the analysis is based on retrospective reports from the people involved and any records produced during the incident. An important extension on this approach is the *critical decision method* (Wong 2004), which focuses on understanding the knowledge involved in making expert-level decisions in difficult situations. However, the critical "incident" might be a major episode of otherwise routine activity that serves especially well to reveal the problems in a system. For example, observation of a highly skilled operator performing a very specialized task revealed that most of the time was spent doing ordinary file maintenance; understanding why led to major improvements in the system (Brooks, personal communication).

33.2.2.3.3 Questionnaires

Questionnaires are a fixed set of questions that can be used to collect some types of user and task information on a large scale quite economically. The main problem is that the accuracy of the data is unknown compared to observation, and can be susceptible to memory errors and social influences. Despite the apparent simplicity of a questionnaire, designing and implementing a successful one is not easy, and can require an effort comparable to interviews or workplace observation.

33.2.2.3.4 Structured Interviews

Interviews involve talking to users or domain experts about the task. Typically, some unstructured interviews might be done first, in which the analyst simply seeks any and all kinds of comments about the task. Structured interviews can then be planned; a series of predetermined questions for the interview is prepared to ensure a more systematic, complete, and consistent collection of information.

33.2.2.4 General Issues in Representing Tasks

Once the task data is collected, the problem for the analyst is to determine how to represent the task data, which requires a decision about what aspects of the task are important and how much detail to represent. The key function of a representation is to make the task structure visible or apparent in some way that supports the analyst's understanding of the task. By examining a task representation, an analyst hopes to identify problems in the task flow, such as critical bottlenecks, inconsistencies in procedures, excessive workloads, and activities that could be better supported by the system. Traditionally,

a graphical representation, such as a flowchart or diagram, has been preferred, but as the complexity of the system and the operating procedures increase, diagrammatic representations lose their advantage.

33.2.2.4.1 Task Decomposition

One general form of task analysis is often termed task decomposition (Kirwan and Ainsworth 1992). This is not a well-defined method at all, but merely reflects a philosophy that tasks usually have a complex structure, and a major problem for the analyst will be to decompose the whole task situation into subparts for further analysis, some of which will be critical to the system design, and others possibly less important. Possible decompositions include controls and their arrangement or display coding. But an especially important approach is to decompose a task into a hierarchy of subtasks and the procedures for executing them, leading to a popular form of analysis called (somewhat too broadly) *Hierarchical Task Analysis* (HTA). However, another approach would be to decompose the task situation into considerations of how the controls are labeled, how they are arranged, and how the displays are coded. This is also task decomposition, and might also have a hierarchical structure, but the emphasis is on describing aspects of the displays in the task situation. Obviously, depending on the specific system and its interface, some aspects of the user's task situation may be far more important to analyze than others. Developing an initial task decomposition can help identify what is involved overall in the user's task, and thus allows the analyst to choose what aspects of the task merit intensive analysis.

33.2.2.4.2 Level of Detail

The question of how much detail to represent in a task analysis is difficult to answer. At the level of whole tasks, Kirwan and Ainsworth (1992) suggest a *probability times cost* rule: if the probability of inadequate performance multiplied by the cost of inadequate performance is low, then the task is probably not worthwhile to analyze. But, even if a task has been chosen as important, the level of detail at which to describe the particular task still must be chosen. Some terminology must be clarified at this point: task decompositions can be viewed as a standard inverted tree structure, with a single item, the overall task, at the top, and the individual actions (such as keystrokes or manipulating valves) or interface objects (switches, gauges) at the bottom. A high-level analysis deals only with the low-detail top parts of the tree, while a low-level analysis includes all of the tree from the top to the high-detail bottom.

The cost of task analysis rises quickly as more detail is represented and examined, but on the other hand, many critical design issues appear only at a detailed level. For example, at a high enough level of abstraction, the Unix operating system interface is essentially just like the Macintosh operating system interface; both interfaces provide the functionality for invoking application programs and copying, moving, and deleting files and directories. The notorious usability problems of the Unix command line relative to the Mac OS X GUI only appear at a level of detail that the cryptic, inconsistent, and clumsy command structure and generally poor feedback come to the surface. "The devil is in the details." Thus, a task analysis capable of identifying usability issues in an interface design typically involves working at a low, fully detailed level that involves individual commands and mouse selections. The opposite consideration holds for the design of functionality, as will be discussed later. When choosing functionality, the question is how the user will carry out tasks using a set of system functions, and it is important to avoid being distracted by the details of the interface.

33.2.2.5 Representing What the User Needs to Know

Another form of task analysis is to represent what knowledge the human needs to have in order to effectively operate the system. Clearly, the human needs to know how to operate the equipment; such procedural knowledge is treated under its own heading in the next section. But, the operator might need additional procedural knowledge that is not directly related to the equipment, and additional nonprocedural conceptual background knowledge. For example, a successful fighter aircraft pilot must know more than just the procedures for operating the aircraft and the onboard equipment; he or she must have additional procedural skills such as combat tactics, navigation, and communication protocols, and

an understanding of the aircraft mechanisms and overall military situation is valuable in dealing with unanticipated and novel situations.

Information on what the user needs to know is clearly useful for specifying the content of operator training and operator qualifications. It can also be useful in choosing system functionality in that large benefits can be obtained by implementing system functions that make it unnecessary for users to know concepts or skills that are difficult to learn; such simplifications typically are accompanied by simplifications in the operating procedures as well. Aircraft computer systems that automate navigation and fuel conservation tasks are an obvious example.

In some cases where the user knowledge is mostly procedural in content, it can be represented in a straightforward way, such as decision–action tables that describe what interpretation should be made of a specific situation, as in an equipment troubleshooting guide. However, the required knowledge can be extremely hard to identify if it does not have a direct and overt relationship to "what to do" operating procedures. An example is the petroleum geologist, who after staring at a display of complex data for some time, comes up with a decision about where to drill, and probably cannot provide a rigorous explanation for how the decision was made. Understanding how and why users make such decisions is difficult, because there is very little or no observable behavior prior to producing the result; it is all "in the head," a *purely cognitive task*.

Analyzing a purely cognitive task in complete detail is essentially a cognitive psychology research project, and so is not usually practical in a system design context. Furthermore, to the extent that a cognitive task can be completely characterized, it becomes a candidate for automation, making the design of the user interface moot. Expert systems technology, when successfully applied using "knowledge acquisition" methods (see Boose 1992), is an example of task analyses carried out in enough detail that the need for a human performer of the task is eliminated.

However, most cognitive tasks seem neither possible nor practical to analyze this thoroughly, but there is still a need to support the human performer with system functions and interfaces and training programs and materials that improve performance in the task even if it is not completely understood. For example, Gott (1988) surveys cases in which an intensive effort to identify the knowledge required for tasks can produce large improvements in training programs for highly demanding cognitive tasks such as electronics troubleshooting.

During the 1990s, there were many efforts to develop methods for cognitive task analysis (CTA). Cognitive task analysis emphasizes the knowledge required for a task, and how it is used in decision-making, situation-recognition, or problem-solving rather than just the procedures involved (see Chipman et al. 2000 for an overview, and Dubois and Shalin 2000 and Seamster et al. 2000 for useful summaries of some important methods). Most CTA methods involve some form of interview techniques for eliciting a subset of the most critical knowledge involved in a task, often focusing on critical incidents (Crandall et al. 2006; Militello and Hutton 2000; Wong 2004).

33.2.2.6 Representing What the User Has to Do

A major form of task analysis is describing the actions or activities carried out by the human operator while tasks are being executed. Such analyses have many uses; the description of how a task is currently conducted, or would be conducted with a proposed design, can be used for prescribing training, assisting in the identification of design problems in the interface, or as a basis for quantitative or simulation modeling to obtain predictions of system performance. Depending on the level of detail chosen for the analysis, the description might be at very high level, or might be fully detailed, describing the individual valve operations or keystrokes needed to carry out a task. The following are the major methods for representing procedures.

33.2.2.6.1 Operational Sequence Diagrams

Operational sequence diagrams and related techniques show the sequence of the operations (actions) carried out by the user (or the machine) to perform a task, represented graphically as a flowchart using

standardized symbols for the types of operations. Such diagrams are often partitioned, showing the user's actions on one side, and machine's on the other, to show the pattern of operation between the user and the machine.

33.2.2.6.2 Hierarchical Task Analysis

Hierarchical task analysis involves describing a task as a hierarchy of tasks and subtasks, emphasizing the procedures that operators will carry out, using several specific forms of description. The term "hierarchical" is somewhat misleading, since many forms of task analysis produce hierarchical descriptions; a better term might be "procedure hierarchy task analysis." The results of an HTA are typically represented either graphically, as a sort of annotated tree diagram of the task structure similar to the conventional diagram of a function-call hierarchy in programming, or in a more compact tabular form. This is the original form of systematic task analysis (Annett et al. 1971) and still the single most heavily used form of task analysis (see Annett 2004 for additional background and procedural guide).

HTA descriptions involve *goals, tasks, operations,* and *plans*. A goal is a desired state of affairs (e.g., a chemical process proceeding at a certain rate). A task is a combination of a goal and a context (e.g., get a chemical process going at a certain rate given the initial conditions in the reactor). Operations are activities for attaining a goal (e.g., procedures for introducing reagents into the reactor, increasing the temperature, and so forth). Plans specify which operations should be applied under what conditions (e.g., which procedure to follow if the reactor is already hot). Plans usually appear as annotations to the tree-structure diagram that explain which portions of the tree will be executed under what conditions. Each operation in turn might be decomposed into subtasks, leading to a hierarchical structure. The analysis can be carried out to any desired level of detail, depending on the requirements of the analysis.

33.2.2.6.3 GOMS Models

GOMS models (John and Kieras 1996a,b), introduced earlier, are closely related to HTA, and in fact Kirwan and Ainsworth (1992) include GOMS as a form of HTA. GOMS models describe a task in terms of a hierarchy of goals and subgoals, methods which are sequence of operators (actions) that when executed will accomplish the goals, and selection rules that choose which method should be applied to accomplish a particular goal in a specific situation. However, both in theory and in practice, GOMS models are different from HTA. The concept of GOMS models grew out of research on human problem-solving and cognitive skills, whereas HTA appears to have originated out of the pragmatic commonsense observation that tasks often involve subtasks, and eventually involve carrying out sequences of actions. Because of its more principled origins, GOMS models are more disciplined than HTA descriptions. The contrast is perhaps most clear in the difficulty HTA descriptions have in expressing the flow of control: the procedural structure of goals and subgoals must be deduced from the plans, which appear only as annotations to the sequence of operations. In contrast, GOMS models represent plans and operations in a uniform format using only methods and selection rules. An HTA plan would be represented as simply a higher-order method that carries out lower-level methods or actions in the appropriate sequence, along with a selection rule for when the higher-order method should be applied.

33.2.2.7 Representing What the User Sees and Interacts With

The set of information objects and controls that the user interacts with during task execution constrain the procedures that the user must follow (Zhang and Norman 1994, 1997). Consequently, a full procedural description of the user's task must refer to all objects in the task situation that the user must observe or manipulate. However, it can be useful to attempt to identify and describe the relevant objects and event independently of the procedures in which they are used. Such a task analysis can identify some potential serious problems or design issues quite rapidly. For example, studies of nuclear power plant control rooms (Woods et al. 1987) found that important displays were located in positions such that they could not be read by the operator. A task decomposition can be applied to break the overall task situation down into smaller portions, and the interface survey technique mentioned earlier can

then determine the various objects in the task situation. Collecting additional information, for example, from interviews or walkthroughs, can then lead to an assessment of whether and under what conditions the individual controls or displays are required for task execution. There are then a variety of guidelines in human factors for determining whether the controls and displays are adequately accessible.

33.2.2.8 Representing What the User Might Do Wrong

Human factors practitioners and researchers have developed a variety of techniques for analyzing situations in which errors have happened, or might happen. The goal is to determine whether human errors will have serious consequences, and to try to identify where they might occur and how likely they are to occur. The design of the system or the interface can then be modified to try to reduce the likelihood of human errors, or mitigate the consequences of them. Some key techniques can be summarized.

33.2.2.8.1 Event Trees

In an event tree, the possible paths, or sequences of behaviors, through the task are shown as a tree diagram; each behavior outcome is represented either as success/failure, or a multiway branch, for example, for the type of diagnosis made by an operation in response to a system alarm display. An event tree can be used to determine the consequences of human errors, such as misunderstanding an alarm. Each path can be given a predicted probability of occurrence based on estimates of the reliability of human operators at performing each step in the sequence these estimates are controversial; see Reason1990 for discussion).

33.2.2.8.2 Failure Modes and Effects Analysis

The analysis of human failure modes and their effects is modeled after a common hardware reliability assessment process. The analyst considers each step in a procedure, and attempts to list all the possible failures an operator might commit, such as to omit the action, perform it too early, too late, too forcefully, and so forth. The consequences of each such failure “mode” can then be worked out, and again a probability of failure could be predicted.

33.2.2.8.3 Fault Trees

In a fault tree analysis, the analyst starts with a possible system failure, and then documents the logical combination of human and machine failures that could lead to it. The probability of the fault occurring can then be estimated, and possible ways to reduce the probability can be determined.

33.2.2.8.4 Application to Computer User Interfaces

Until recently, these techniques had not been applied in computer user interface design to any visible extent. At most, user interface design guides contained a few general suggestions for how interfaces could be designed to reduce the chances of human error. Promising work such as Stanton and Baber (2005) and Wood (1999), use task analysis as a basis for systematically examining how errors might be made and how they can be detected and recovered from. Future work along these lines will be an extraordinarily important contribution to system and interface design.

33.3 Design of Functionality

33.3.1 Principles

Given a task analysis that describes how the work is done currently, can a new system be designed that will enable the work to be done more quickly, efficiently, reliably, or accurately? Such improvement usually involves changes in *function allocation*—assigning functions to the human and the computer—in ways different from how it is currently being done. For example, if an existing process for selling and shipping merchandise involves only paper documents, and a computer-supported process is desired, then it is necessary to choose a role for the computer in terms of its functions. For example, these could merely allow the same forms to be filled out on the computer screen and then printed out and handled

manually, or the completed forms could be handled electronically, or the work process redesigned so that no forms need to be filled out at all. Each allocation of machine functions implies a corresponding and complementary allocation of human user functions.

The design of functionality is closely related to task analysis. One must start with an analysis of the existing tasks, considered as the whole work process, and then propose new machine functionality that will improve the existing task or work process; this new version of the task must then be analyzed to determine if there has been a net benefit, and whether additional benefits could be obtained by further redesign of the process.

33.3.1.1 Problems with the Current Situation

In many software development organizations, some groups, such as a marketing department or government procurement agents, prepare a list of requirements for the system to be developed. Such requirements specify the system functions at least in part, typically in the form of lists of desired features. The designers and developers then further specify the functions, possibly adding or deleting functions from the list, and then begin to design an implementation for them. Problems with misdefined functionality are common, because the typical processes for preparing requirement specifications often fail to include a substantial task analysis.

Typically, only after this point is the user interface design begun. The design of the user interface may use appropriate techniques to arrive at a usable design, but these techniques normally are based on whatever conception of the user and the user's tasks have already been determined, and the interface is designed in terms of the features or functions that have already been specified. Thus, even when a usability process is followed, it might well arrive at only a local optimum defined by an inadequate characterization of the user's needs and the corresponding functions (cf. Buxton 2007).

That is, the focus of usability methods tends to be on relatively low-level questions (such as menu structure) and on how to conduct usability tests to identify usability problems; the problem is posed as developing a usable interface to functions that have already been chosen. Typically, the system requirements have been prepared by a group which then "throws it over the wall" to a development group who arrives at the overall design and functional implementation, and then throws it over the wall to a usability group to "put a good interface on it."

The problem is that if the initial requirements and system functions are poorly chosen, the rest of the development will probably fail to produce a usable product. It is a truism in HCI that if customers need the functionality, they will buy and use even a clumsy, hard-to-use product. If the functionality is poorly chosen, no amount of effort spent on user interface design will result in a usable system, and it might not even be useful at all. This is by no means a rare occurrence; it is easy to find cases of poorly chosen functionality that undermine whatever usability properties the system otherwise possesses. Some classic examples are as follows.

33.3.1.1.1 Interface Is Often Not the Problem

An important article with this title by Goransson et al. (1987) presents several brief case studies that involve failures of functionality design masquerading as usability problems. The most painful is a database system in a business organization that was considered to be too difficult to use. The interface was improved to make the system reasonably easy to use, but then it became clear that nobody in the organization needed the data provided by the system! Apparently, the original system development did not include an analysis of the needs of the organization or the system users. The best way to improve the usability of the system would have been to simply remove it.

33.3.1.1.2 Half a Loaf Is Worse Than None

The second major version of an otherwise easy-to-use basic word processing application included a multiple-column feature; however, it was not possible to mix the number of columns on a page. Note that documents having a uniform layout of two or three columns throughout are rare in the real world; rather, real multicolumn documents almost always mix the number of columns on at least one page. For example,

a common pattern is a title page with a single column for the title that spans the page, followed by the body of the document in two-column format. The application could produce such a document only if two separate documents were prepared, printed, and then physically cut-and-pasted together! In other words, the multiple-column feature of this second version was essentially useless for preparing real documents. A proper task analysis would have determined the kinds and structures of multiple-column documents that users would be likely to prepare. Using this information during the product development would have led to either more useful functionality (like the basic page-layout features in the third major release of the product), or a decision not to waste resources on a premature implementation of incomplete functionality.

33.3.1.1.3 Why Doesn't It Do That?

A first-generation handheld "digital diary" device provided calendar and date book functions equivalent to paper calendar books, but included no clock, no alarms, and no awareness of the current date, although such functions would have been minor additions to the hardware. In addition, there was no facility for scheduling repeating meetings, making such scheduling remarkably tedious. The only shortcut was to use a rather clumsy copy–paste function, but it did not work for the meeting time field in the meeting information. A task analysis of typical user's needs would have identified all of these as highly desirable functions. Including them would have made the first generation of these devices much more viable.

33.3.1.1.4 Progress Is Not Necessarily Monotonic

The second version of an important Personal Digital Assistant also had a problem with recurring meetings. In the first version, a single interface dialog was used for specifying recurring meetings, and it was possible to select multiple days per week for the repeating meeting. Thus, the user could easily specify a weekly repeating meeting schedule of the sort common in academics, for example, scheduling a class that meets at the same time every Monday, Wednesday, and Friday for a semester. However, in the second version, which attempted many interface improvements, this facility moved down a couple of menu levels and became both invisible in the interface (unless a certain option was selected) and undocumented in the user manual. If any task analysis was done in connection with either the original or second interface design, it did not take into account the type of repeating meeting patterns needed in academic settings, a major segment of the user population that includes many valuable "early adopter" customers.

33.3.1.1.5 Missing Functions Can Be Hazardous to Your Health

The aforementioned are examples of missteps made long ago. However, poorly designed functionality is still common, even in the currently active and important field of health information systems. For example, at a major eye surgery clinic, a key part of the patient record is sketches on a paper form that are hand-drawn by the retina specialists during slit-lamp ophthalmoscopy examinations. These sketches show internal features of the patient's eyes that even modern imaging techniques cannot adequately convey. A new computer-based record system being installed has no provision for input or storage of such sketches. How will this be handled without degrading patient care, requiring additional personnel, or disrupting the workflow of these medical experts?

33.3.2 Best Practices: How to Design Functionality

33.3.2.1 Task Analysis at the Whole-System Level

When large systems are being designed, an important component of task analysis is to consider how the system, consisting of all the machines, and all the humans, is supposed to work as a whole in order to accomplish the overall system goal.

In the military systems, often analyzed heavily in Human Factors, the overall system goal is normally rather large-scale and well above the level of concerns of the individual humans operating the machines. For example, in designing a new naval fighter aircraft, the system goals might be stated in terms such as "enable air superiority in naval operations under any conditions of weather and all possible combat

theaters through the year 2020." At this level, the "users" of the system as a whole are military strategist and commanders, not the pilot, and the system as a whole will involve not just the pilot, but other people in the cockpit (such as a radar intercept operator), and also maintenance and ground operations personnel. Thus, the humans involved in the system will have a variety of goals and tasks, depending on their role in the whole system.

At first glance, this level of analysis would appear to have little to do with computer systems; we often think of computer users as isolated individuals carrying out their tasks by interacting with their individual computers. However, when considering the needs of an organization, the mission level of analysis is clearly important; the system is supposed to accomplish something as a whole, and the individual humans all play roles defined by their relationship with each other and with the machines in the system. HCI has begun to consider higher levels of analysis, as in the field of computer-supported collaborative work, but perhaps the main reason why the mission level of analysis is not common parlance in HCI is that HCI has a cultural bias that organizations revolve around humans, with the computers playing only a supporting role. Such a bias would explain the movement mentioned earlier toward incorporating more social-science methodology into system design. In contrast, in military systems, the human operators are often viewed as "parts" in the overall system, whose ultimate "user" is the commanding officer, leading to a concern with how the humans and machines fit together. Only after due regard for this whole-system perspective, which provides the context for the activities of individual humans, is it then possible to properly consider what goals the individual operators will need to accomplish and how their machines will support them.

This kind of very high-level analysis can be done even with very large systems, such as military systems involving multiple machines and humans. The purpose of the analysis is to determine what role in the whole system the individual human operators will play. Various methods for whole-system analysis have been in routine use for some time. Briefly, these are as follows (see Beevis et al. 1992; Kirwan and Ainsworth 1992).

33.3.2.1.1 Mission and Scenario Analysis

Mission and scenario analysis is an approach to starting the system design from a description of what the system has to do (the mission), especially using specific concrete examples, or scenarios (see Beevis et al. 1992 for related discussion).

33.3.2.1.2 Function-Flow Diagrams

Function-flow diagrams are constructed to show sequential or information-flow relationships of the functions performed in the system. Beevis et al. (1992) provide a set of large-scale examples, such as naval vessels.

33.3.2.1.3 Function Allocation

Function allocation is a set of fairly informal techniques for deciding which system functions should be performed by machines, and which by people. Usually mentioned in this context is the *Fitts list* that describes what kinds of activities can be best performed by humans versus machines (Beevis et al. 1992). Two examples for humans are the ability to perceive patterns and make generalizations about them, and to react to unexpected low-probability events. Two examples for machines are performing repetitive and routine tasks, and doing many different things at one time. However, according to surveys described in Beevis et al. (1992), this classic technique is rarely used in real design problems since it is simply not specific enough to drive design decisions. Rather, functions are typically allocated in an ad hoc manner, often simply maintaining whatever allocation was used in the predecessor system, or following the rule that whatever can be automated should be, even though it is known that automation often produces safety or vigilance problems for human operators (Kantowitz and Sorkin 1987). There have been some attempts to make function allocation more systematic (see Sheridan, Woods, Pew, and Hancock 1998 for an overview), but at least when it comes to computer system design, methods both new and still under development must be relied upon.

As argued earlier, the key feature of computer-based tasks is the dominance of procedural aspects of the task; this means that function allocation approaches that are based on the task procedures are mostly likely to be valuable in the design of functionality. Thus, function allocation decisions are best driven by consideration of the task procedures; a good function allocation will be characterized by fast, simple, and efficient procedures for the user to follow with a minimum of overhead imposed by the use of the machine. The next sections describe some developing approaches to function allocation and functionality design.

33.3.2.2 Using GOMS Task Analysis in Functionality Design

The task analysis techniques described previously work well enough to have been developed and applied in actual system design contexts. However, they have mainly developed in the analysis of traditional interface technologies rather than computer user interfaces. While as discussed earlier, the general concepts of task analysis hold for computer interfaces, there are some key differences and a clear need to address computer user interfaces more directly. In summary, the problems with traditional task representations are as follows:

1. Computer interface procedures tend to be complicated, repetitious, and hierarchical. The primarily graphical and tabular representations traditionally used for procedures become unwieldy when the amount of detail is large.
2. They use different representation approaches for procedures that differ only in the level of analysis. For example, in HTA, a plan is represented differently from a procedure, even though a plan is simply a kind of higher-order procedure.
3. To a great extent, Human Factors practice uses different representations for different stages of the design process (see Beevis et al. 1992; Kirwan and Ainsworth 1992). It would be desirable to have a single representation that spans these stages even if it only covers part of the task analysis and design issues.

This section describes how GOMS models could be used to represent a high-level task analysis that can be used to help choose the desirable functionality for a system. Because GOMS models have a programming-language-like form, they can represent large quantities of procedural detail in a uniform notation that works from a very high level down to the lowest level of the interface design.

33.3.2.3 High-Level GOMS Analysis

Using high-level GOMS models is an alternative to the conventional requirements development and interface design process discussed in the introduction to this chapter. The approach is to drive the choice of functionality from the high-level procedures for doing the tasks, choosing functions that will produce simple procedures for the user. By considering the task at a high level, these decisions can be made independently of, and prior to, the interface design, thereby improving the chances that the chosen functionality will enable a highly useful and usable product once a good interface is developed. The analyst can then begin to elaborate the design by making some interface design decisions and writing the corresponding lower-level methods. If the design of the functionality is sound, it should be possible to expand the high-level model into a more detailed GOMS model that also has simple and efficient methods. If desired, the GOMS model can be fully elaborated down to the keystroke level of detail that can produce usability predictions (see John and Kieras 1996a,b; Kieras 1997).

GOMS models involve goals and operators at all levels of analysis, with the lowest level being the so-called keystroke level, of individual keystrokes or mouse movements. The lowest level goals will have methods consisting of keystroke-level operators, and might be basic procedures such as moving an object on the screen, or selecting a piece of text. However, in a high-level GOMS model, the goals may refer only to parts of the user's task that are independent of the specific interface, and may not specify operations in the interface. For example, a possible high-level goal in creating a document would be *Add a footnote*, but not *Select insert footnote from edit menu*. Likewise, the operators must be well above the keystroke level of detail, and not be specific interface actions. The lowest level of detail an operator may

have is to invoke a system function, or perform a mental decision or action such as choosing which files to delete or thinking of a file name. For example, an allowable operator would be *Invoke the database update function*, but not *Click on the update button*.

The methods in a high-level GOMS model describe the order in which mental actions or decisions, submethods, and invocations of system functions are executed. The methods should document what information the user needs to acquire in order to make any required decisions and invoke the system functions, and also should represent where the user might detect errors and how they might be corrected with additional system functions. All too often, support for error detection and correction by the user is either missing, or is a clumsy add-on to a system design; by including it in the high-level model for the task, the designer may be able to identify ways in which errors can be prevented, detected, and corrected, early and easily.

33.3.2.3.1 An Example of High-Level GOMS Analysis

33.3.2.3.1.1 Task Domain The domain for this example is electronic circuit design and computer-aided design systems for electronic design (ECAD). A task analysis of this domain would reveal many very complex activities on the part of electronic circuit designers. Of special interest are several tasks for which computer support is feasible: After a circuit is designed, its correct functioning must be verified, and then its manufacturing cost estimated, power and cooling requirements determined, the layout of the printed circuit boards designed, automated assembly operations specified, and so forth.

This example involves computer support for the task of verifying the circuit design by using computer simulation to replace the traditional slow and costly "breadboard" prototyping. For many years, computer-based tools for this process have been available and undergoing development, based on the techniques for simulating the behavior of the circuit using an abstract mathematical representation of the circuit. For purposes of this example, attention will be limited to the somewhat simpler domain of digital circuit design. Here, the components are black-box modules (i.e. integrated circuits, "chips") with known behaviors, and the circuit consists simply of these components with their terminals interconnected with wires. Thus, the basic task goal for this example is to arrive at a correctly functioning circuit—a configuration of interconnected chips that performs the required function.

However, the user can make errors in performing the task; in this domain, the user errors can be divided into *semantic* errors, in which the specified circuit does not do what it is supposed to do, and *syntactic* errors, in which the specified circuit is invalid, regardless of the function. The semantic errors can only be detected by the user evaluating the behavior of the circuit, and discovering that the idea for the circuit was incorrect or incorrectly specified. In fact, the basic concept of the ECAD simulator is to support finding and correcting the semantic errors, so these are already being accounted for. The syntactic errors in the digital circuit domain are certain connection patterns that are incorrect just in terms of what is permissible and meaningful with digital logic circuits. Two common cases are disallowed connections (e.g., shorting an output terminal to ground) or missing connections (e.g., leaving an input terminal unconnected). It is important to correct syntactic errors prior to running the simulator, because their presence will cause the simulator to fail or produce invalid results.

The high-level functionality design of an actual system will be illustrated; then to show how the analysis can lead to design improvements, a better design will be illustrated.

33.3.2.3.1.2 High-Level GOMS Model The basic functionality concept is using a simulation of a circuit to verify the circuit design. This concept is described in the *top-level method*, which is the first method shown in Figure 33.1, which accomplishes the goal *Verify circuit with ECAD system*. This first method needs some explanation of the notation, which is the "Natural" GOMS Language (NGOMSL) described by Kieras (1997) for representing GOMS models in a relatively nontechnical readable format. The first line introduces a method for accomplishing the top-level user goal. It will be executed whenever the goal is asserted, and terminates when the return with goal accomplished operator in Step 4 is executed. Step 1 represents the user's "black-box" mental activity of thinking up the original idea for the circuit design; this think-of operator is just a placeholder; no attempt is made to represent the extraordinarily complex

```
Method for goal: Verify circuit with ECAD system
    Step 1. Think-of circuit idea.
    Step 2. Accomplish Goal: Enter circuit into ECAD system.
    Step 3. Accomplish Goal: Proofread drawing.
    Step 4. Invoke circuit simulation function and get results.
    Step 5. Decide: If circuit performs correct function,
                 then return with goal accomplished.
    Step 6. Think-of modification to circuit.
    Step 7. Make modification with ECAD system.
    Step 8. Go to 3.

Method for goal: Enter circuit into ECAD system
    Step 1. Invoke drawing tool.
    Step 2. Think-of object to draw next.
    Step 3. If no more objects, then Return with goal accomplished.
    Step 4. Accomplish Goal: draw the next object.
    Step 5. Go to 2.

Selection rule set for goal: Drawing an object
    If object is a component, then accomplish Goal: draw a component.
    If object is a wire, then accomplish Goal: draw a wire.
    ...
    Return with goal accomplished

Method for goal: Draw a component
    Step 1. Think-of component type.
    Step 2. Think-of component placement.
    Step 3. Invoke component-drawing function with type and placement.
    Step 4. Return with goal accomplished.

Method for goal: Draw a wire
    Step 1. Think-of starting and ending points for wire.
    Step 2. Think-of route for wire.
    Step 3. Invoke wire-drawing function with starting point,
                 ending point, and route.
    Step 4. Return with goal accomplished
```

FIGURE 33.1 High-level methods for ECAD system.

cognitive processes involved. Step 2 asserts a subgoal to specify the circuit for the ECAD system by entering the circuit into the system; the method for this subgoal appears next in Figure 33.1. Step 3 of the top-level method asserts a subgoal to proofread the entered circuit to find and correct the syntactic errors. Step 4 is a high-level operator for invoking the functionality of the circuit simulator and getting the results; no commitment is made at this point to how this will be done; the method merely asserts that there is a function to do this. Step 5 documents that at this point the user will decide whether the job is complete or not based on the output of the simulator. If not, Step 6 is another placeholder for a complex cognitive process of deciding what modification to make to the circuit. Step 7 invokes the functionality to modify the circuit, which would probably be much like that involved in Step 2, but which will not be further elaborated in this example. Finally, the loop at Step 8 shows that the top-level task is iterative.

At this point, the top-level method shows the basic structure of how the ECAD system will work: the user inputs a circuit specification, checks the specification for entry errors, runs the simulation, interprets the results, and modifies the circuit and repeats if necessary. Notice that the iteration in the top-level method provides for detecting and correcting semantic errors in the circuit concept. This basic design is motivated by a function allocation: only the human user knows how the circuit must behave, and what candidate circuit might accomplish that behavior, so these parts of the process are performed by the human. However,

the computer can simulate the behavior of the circuit much faster and more reliably than a human could, so it performs this function. This basic function allocation insight is the motivation for developing the system.

The methods must be expanded to show how the top-level steps will get done. First, consider the method for entering a circuit into the ECAD system. In this domain, schematic circuit drawings are the conventional representations for a circuit, so a good choice of functionality for entering the candidate circuit information is a tool for drawing circuit diagrams that also produces the data representation needed for the simulation. This is reflected in the method for the goal *Enter circuit into ECAD system*.

This method starts with invoking the drawing tool, and then has a simple iteration consisting of thinking of something to draw, accomplishing the goal of drawing it, and repeating until done. The methods get more interesting when the goal of drawing an object is considered, because in this domain there are some fundamentally different kinds of objects, and the information requirements for drawing them are different. Only two kinds of objects will be considered here.

A selection rule is needed in a GOMS model to choose what method to apply depending on the kind of object, and then a separate method is needed for each kind of object; the selection rule set in Figure 33.1 thus accomplishes a general goal by asserting a more specific goal, which then triggers the corresponding method. The method for drawing a component requires a decision about the type of component (e.g., what specific multiplexer chip should be used) and where in the diagram the component should be placed to produce a visually clear diagram; the drawing function for a component creates the appropriate graphical representation of the component. Drawing a connecting wire requires deciding which two points in the circuit the wire should connect, and then choosing a route for the wire to produce a clear appearance in the diagram.

At this point, the analysis has revealed some possibly difficult and time-consuming user activities; candidates for additional system functions to simplify these activities could be considered. For example, the step of thinking of an appropriate component might be quite difficult, due to the huge number of integrated circuits available, and likewise thinking of the starting and ending points for the wire involves knowing which input or output function goes with each of the many pins on the chips. Some kind of online documentation or database to provide this information in a form that meshes well with the task might be valuable. Likewise, a welcome function might be some automation to choose a good routing for wires.

Next to be considered is how the goal of proofreading the circuit would be accomplished. In the actual design presented here, the functionality decisions were apparently motivated by simple after-the-fact "add-ons." As shown in Figure 33.2, the method for proofreading the drawing first invoked a checking

```
Method for goal: Proofread drawing
    Step 1. Invoke checking function and get list of error messages.
    Step 2. Look at next error message.
    Step 3. If no more error messages, Return with goal accomplished.
    Step 4. Accomplish Goal: Process error message.
    Step 5. Go to 2.

Method for goal: Process error message
    Step 1. Accomplish Goal: Locate erroneous point in circuit.
    Step 2. Think-of modification to erroneous point.
    Step 3. Make modification to circuit.
    Step 4. Return with goal accomplished.

Method for goal: Locate erroneous point in circuit
    Step 1. Read type of error, netlist node name from error message.
    Step 2. Invoke identification function with netlist node name.
    Step 4. Locate highlighted portion of circuit.
    Step 5. Return with goal accomplished.
```

FIGURE 33.2 Diagram of proofreading methods for an actual ECAD system.

function, which was designed to produce a series of error messages that the user would process one at a time. For ease in implementation, the checking function did not work in terms of the drawing, but in terms of the abstract circuit representation, the "netlist," and so reported the site of the syntactically illegal circuit feature in terms of the name of the "node" in the netlist. However, the only way the user had to examine and modify the circuit was in terms of the schematic diagram. So, the method for processing each error message requires first locating the corresponding point in the circuit diagram, and then making a modification to the diagram. To locate the site of the problem on the circuit diagram, the user invoked an identification function and provided the netlist node name; the function then highlights the corresponding part of the circuit diagram, which the user can then locate on the screen. Only then can the user think of what the problem is and how to correct it. In summary, this set of functionality design decisions means that in order to check the diagram for errors, the user must first complete the entire diagram, and then invoke a function, which produces output for each error that must be manually transferred into another function to identify the location of the error on the diagram.

Although no specific details of the interface have yet been specified, the high-level methods clearly point to a usability problem in the making: a clumsy iterative process must be performed just to make syntactic errors visible in a natural way. This design could be dismissed as a silly example, except for the fact that at least one major vendor of ECAD software used exactly this design.

Are there alternative functionality designs that would simplify the proofreading process? Certainly, combining the checking and identification functions would remove the need to manually transfer the netlist node name between the two device functions; the user could view the error message and the highlighted part of the circuit diagram simultaneously. However, a bit more analysis suggests that a different function allocation might be much better. In particular, rather than allow the user to complete a diagram that contains errors which are then detected and corrected, it would be desirable to allow errors to be detected and corrected during the drawing; the proofreading functionality would be moved from the top-level method into the circuit-entry method and its submethods. In this domain, disallowed connections appear at the level of individual wires, while missing connections show up at the level of the entire diagram. Thus, the functions to assist in detecting and correcting disallowed connections should be operating while the user is drawing wires, and those for missing connections while the user is working on the whole drawing. Figure 33.3 shows the corresponding revised methods. In this version, the function for drawing a wire checks for disallowed connections and thus enables their correction immediately; proofreading the entire diagram has been moved from the top-level method to the method for entering the circuit, and involves detecting missing connections and correcting them by drawing a wire.

At this point in the design of functionality, the analysis has documented what information the user needs to get about syntactic errors in the circuit diagram, and where this information could be used to detect and correct the error immediately. Some thought can now be given to what interface-level functionality might be useful to support the user in finding syntactically missing and disallowed connections. One obvious candidate is to use color-coding; for example, perhaps unconnected input terminals could start out as red in color on the display, and then turn green when validly connected. Likewise, perhaps as soon as a wire is connected at both ends, it could turn red if it is a disallowed connection, and green if it is legal. This use of color should work very well, since properly designed color-coding is known to be an extremely effective way to aid visual search. In addition, the color-coding calls the user's attention to the problems but without forcibly interrupting the user. This design rationale for using color is an interesting contrast to the actual ECAD system display, which generally made profligate use of color in ways that lacked any obvious value in performing the task. Figure 33.4 presents a revision of the methods to incorporate this preliminary interface design decision.

33.3.2.3.1.3 Implications The previous example of how the design of functionality can be aided by working out a high-level GOMS model of the task seems straightforward and unremarkable. A good design is usually intuitively "right," and once presented, seems obvious. However, at least the first few generations of ECAD tools did not implement such an "intuitively obvious" design at all, probably because nothing

```
Method for goal: Verify circuit with ECAD system
    Step 1. Think-of circuit idea.
    Step 2. Accomplish Goal: Enter circuit into ECAD system.
    Step 3. Invoke circuit simulation function and get results.
    Step 4. Decide: If circuit performs correct function, then
                  return with goal accomplished.
    Step 5. Think-of modification to circuit.
    Step 6. Make modification with ECAD system.
    Step 7. Go to 3.

Method for goal: Enter circuit into ECAD system
    Step 1. Invoke drawing tool.
    Step 2. Think-of object to draw next.
    Step 3. Decide: If no more objects, then go to 6.
    Step 4. Accomplish Goal: draw the next object.
    Step 5. Go to 2.
    Step 6. Accomplish Goal: Proofread drawing.
    Step 7. Return with goal accomplished.

Method for goal: Proofread drawing
    Step 1. Find missing connection in drawing.
    Step 2. Decide: If no missing connection, return with goal
            accomplished.
    Step 3. Accomplish Goal: Draw wire for connection.
    Step 4. Go to 1.

Method for goal: Draw a wire
    Step 1. Think-of starting and ending points for wire.
    Step 2. Think-of route for wire.
    Step 3. Invoke wire drawing function with starting point,
                  ending point, and route.
    Step 4. Decide: If wire is not disallowed, return with goal
            accomplished.
    Step 5. Correct the wire.
    Step 6. Return with goal accomplished.
```

```
Method for goal: Proofread drawing
    Step 1. Find a red terminal in drawing.
    Step 2. Decide: If no red terminals, return with goal accomplished.
    Step 3. Accomplish Goal: Draw wire at red terminal.
    Step 4. Go to 1.

Method for goal: Draw a wire
    Step 1. Think-of starting and ending points for wire.
    Step 2. Think-of route for wire.
    Step 3. Invoke wire drawing function with starting point,
                  ending point, and route.
    Step 4. Decide: If wire is now green, return with goal accomplished.
    Step 5. Decide: If wire is red, think-of problem with wire.
    Step 6. Go to 1.
```

FIGURE 33.4 Methods incorporating color-coding for syntactic drawing errors.

like a task and functionality analysis was performed. Rather, a first version of the system was probably designed and implemented in which the user draws a schematic diagram in the obvious way, and then runs the simulator on it. However, once the system was in use, it became obvious that errors could be made in the schematic diagram that would cause the simulation to fail or produce misleading results. The solution was minimal add-ons of functionality, leaving the original flawed design of functionality intact.

In summary, the high-level GOMS model clarifies the difference between the two designs by showing the overall structure of the interaction. Even at a very high level of abstraction, a poor design of functionality can result in task methods that are obviously inefficient and clumsy. Thus, high-level GOMS models can capture critical insights from a task analysis to help guide the initial design of a system and its functionality. As the design is fleshed out, the high-level GOMS models can be elaborated into methods for a specific proposed interface, so that a good design of both functionality and interface can be developed prior to usability testing, providing a seamless pathway from initial design concept to final detailed design.

33.3.2.4 Work-Centered Design

High-level GOMS models show how a specific set of proposed functions would be used by a user to accomplish tasks. Intuitively, a good choice of functionality would be revealed by the high-level GOMS methods being simple and apparently easy for users to learn and execute. Rather than propose some functionality and then see how well it plays out in detail for the user, a better approach would be to design both the functionality and the user methods concurrently; that is, the design of the top-level interaction of the user and system should be the explicit goal of the system design. This approach was first presented by Butler et al. (1999), followed by a specific application reported by Butler et al. (2007). The approach is called work-centered design (WCD), because the focus has moved upward and outward from the user to the entire work process.

WCD is an approach for systematically designing the functionality and user processes as two complementary parts of a complex system; the name reflects a change in orientation—rather than *user-centered design* which focuses on the users and their needs, it focuses instead on the nature of the work to be done, and seeks to determine the combination of system and user activity that will enable the work to get done most effectively. It thus directly addresses the problem that most system development is *feature-based*; as mentioned earlier, the requirements for a system typically consist of a list of features, whose relation to the work to be done is rarely made explicit, and is often only haphazardly related to the user's tasks. In fact, users normally must *infer* how to use the system features to get the work done; they are often left in the position of being responsible for the "leftovers"—whatever bits of the process did not happen to be allocated to the computer systems. Typically, the resulting overly complex systems do not support the work very well. WCD proposes that instead, the system development process should deliberately focus on the design of the *Top-Level Algorithm* (TLA), the basic pattern of work division between the system and the user.

WCD combines ideas from business process modeling, industrial engineering, software engineering, mission-level task analysis, and the function allocation concept. WCD treats the user(s) and machine(s) of HCI as different types of agent resources, which perform their respective procedures. Taken together, their procedures must constitute a TLA that is capable of transforming the entity (product) of work to its goal state. The key idea is to perform a deliberate design of the top-level interaction between the user and the system in order to allocate functions to the user and system in a way that will optimize the overall workflow, while minimizing overhead tasks for users. The basic steps in WCD process are as follows:

1. *Characterize the work domain*: Similar to the high-level GOMS analysis, WCD takes a whole-system view. It begins by asking the purpose of the system—what has to get done? More specifically, what is the entity of work that the system must produce, independently of how the system will do it? WCD introduces conceptual knowledge as a complement to the procedural knowledge

in task analysis. Adapting a concept from industrial engineering, WCD explicitly specifies the entity of work that the system must produce. Similar to Contextual Research, WCD acknowledges the way the context in which work is performed constrains the procedures of humans and machines. For example, factors such as laws or organizational rules, or spatial separation of agents, must be taken into account if the procedures are to succeed.

2. WCD then asks what operations must be performed to produce that final result? In WCD, transforming the work entity to its goal state is a fundamental requirement for the TLA. For example, consider the problem of mission and maintenance scheduling for an Air Force Transport Squadron presented by Butler et al. (2007). The basic objects in the work entity are aircraft that must be maintained, and missions that need to be performed. The final product of the work is a combined schedule for flight operations and maintenance actions that as much as possible enables all the missions to be flown and all the maintenance to be performed in a timely way. The basic operation in the work domain is assigning time slots for planes when they can be assigned to missions or they will be assigned to maintenance. The assignments are constrained to satisfy all mission and maintenance activities within their needed time windows. The basic constraints are the mission time requirements, the maintenance schedule time requirements, and the maintenance resources available. If these constraints conflict, only designated humans are authorized to make exceptions to the mission or schedule requirements.

   The basic methodology for collecting this information is the task-analysis methods described earlier. But since the goal of the design effort is to produce a good human–machine function allocation and interaction, the emphasis is on characterizing the procedural aspects of the task, such as describing the workflow with a process-modeling tool such as BPMN (White and Miers 2008), a flowchart-like notation that shows the activities and interactions of each actor or system involved. This is similar to the form of operational sequence diagrams in which each actor/system has a "swim lane" and the interaction between these actors/systems is made explicit.

   In addition, it is essential to characterize the entity or entities that are being modified by the process. In the squadron-scheduling domain, a form of ontology model was useful to characterize the kinds of entities, how they could be modified, and the properties of a solution to the scheduling problem. Ideally, this initial characterization of the work to be done can avoid commitments to what part is done by humans versus machines even in the case of an existing system.

3. *Allocate the functions and design the TLA*: Given the operations that must be performed to transform the entity to its goal state, determine which parts of them should be done by humans, and which by machines, and how the work process will sequence human and machine functions to accomplish the work. What is feasible for the machine to do? What must be reserved for the human? If the process is already in place with allocated functions, should it be changed? Are there nonessential, overhead tasks that can be eliminated or reduced?

   Continuing the squadron-scheduling example, the first major step is that the computer system will automatically assign aircraft to missions and maintenance operations as long as both mission requirements and maintenance constraints can be met. However, if they cannot, then the second major step is that humans must decide in a socially determined chain of command whether maintenance actions can be postponed in order to meet the mission requirements, or whether the mission requirements can be modified to meet the maintenance requirements. The third major step is to input these decisions into the machine, which will then finalize the schedule. The sequence, or workflow, in which the machine and human functions interact is described by the TLA.

4. *Assess the quality of the TLA*: How effective is the proposed combination of process and function allocation? A *correct* TLA ensures that the work goals are accomplished—the correct work products are produced. If not, the process and functions must be corrected. An *efficient* TLA has an optimum human–machine function allocation that minimizes the overhead (unnecessary work) and that humans are not performing work that could be done by the machine. This goes beyond simple record-keeping and automation of complex functions such as optimization. For example,

well-designed displays will require less cognitive effort to interpret, and thus eliminate unnecessary work; but the functionality behind computing the required content must be designed. Other overhead issues show up in procedures that are complex, difficult to learn, or impose memory load. If the low-level details of the user interface are well-designed, an efficient TLA will be apparent in usability testing.

But, designing a user interface for a poor TLA is wasted effort; so, some means of evaluating the quality of the TLA prior to interface development is valuable. Task network simulations or high-level GOMS models can provide rough predictions of task performance times or user workloads. If the TLA has problems, then return to Step 2 and attempt to devise a different process or function allocation.

For example, at one point in the development of the squadron scheduling system, a high-level GOMS analysis showed that there was a high overhead user function involving multiple inspections of the individual aircraft information to determine the final schedule. Once seen, it was easy to assign this particular function to the optimization software, resulting in the disappearance of a large amount of user overhead effort. A less formal example was the realization that the human authorized to make changes to the maintenance or mission requirements was not a direct user of the system; so the TLA had to be modified to include using a report-generating function to produce a concise description of the schedule conflict to be given to the decision-maker.

WCD changes the focus from user interface design to the design of effective and efficient work procedures. Once a good TLA has been designed, techniques and guidelines for good user interface design can be applied to complete the design of the user's side of the system. In the case of the squadron scheduling system, the resulting design in its first user testing iteration enabled a single user to successfully complete in less than a half-hour the work that previously required 3 days of work by three experienced users (Butler et al. 2007). Thus, WCD techniques for task analysis and design of functionality can lead to system designs whose quality is high on the first testable version, a great advantage in the development of complex systems. Work is underway to further develop the approach and supporting tools for designing health information systems (Butler et al. 2011).

33.4 Research Issues and Concluding Summary

The major research problem in task analysis is attempting to bring some coherence and theoretical structure to the field. While psychology as a whole, rather seriously, lacks a single theoretical structure, the subfields most relevant to human–system interaction are potentially unified by work in cognitive psychology on cognitive architectures, which are computational modeling systems that attempt to provide a framework for explaining human cognition and performance (see Byrne 2003 for an overview). These architectures are directly useful in system design in two ways: First, because the architecture must be "programmed" to perform the task with task-specific knowledge, the resulting model contains the content of a full-fledged task analysis, both the procedural and cognitive components. Thus, constructing a cognitive-architectural model is a way to represent the results of a task analysis and verify its completeness and accuracy. Second, because the architecture represents the constants and constraints on human activity (such as the speed of mouse pointing movements and short-term memory capacity), the model for a task is able to predict performance on the task, and so can be used to evaluate a design very early in the development process (see Kieras 2012 for an overview).

The promise is that these comprehensive cognitive architectures will encourage the development of coherent theory in the science base for HCI and also provide a high-fidelity way to represent how humans would perform a task. While some would consider such predictive models as the ultimate form of task analysis (Annett and Stanton 2000b), there is currently a gap between the level of detail

required to construct such models and the information available from a task analysis, both in principle and in practice (Kieras and Meyer 2000); there is no clear pathway for moving from one of the well-established task analysis methods to a fully detailed cognitive-architectural model. It should be possible to bridge this gap, because GOMS models, which can be viewed as a highly simplified form of cognitive-architectural model (John and Kieras 1996a,b), are similar enough to HTA that it is easy to move from this most popular task analysis to a GOMS model. Future work in this area should result in better methods for developing high-fidelity predictive models in the context of more sophisticated task analysis methods.

Another area of research concerns the analysis of team activities and team tasks. A serious failing of conventional psychology and social sciences in general is a gap between the theory of humans as individual intellects and actors and the theory of humans as members of a social group or organization. This leaves HCI as an applied science without an articulated scientific basis for moving between designing a system that works well for an individual user and designing a system that meets the needs of a group. Despite this theoretical weakness, task analysis can be done for whole teams with some success, as shown by Essens et al. (2000), Klein (2000), and Zachary et al. (2000). What is less clear at this point is how such analyses can be used to identify an optimum team structure or interfaces to optimally support a team performance. One approach will be to use computational modeling approaches that take individual human cognition and performance into account as the fundamental determiner on the performance of a team (Kieras and Santoro 2004).

While there are serious practical problems in performing task analysis, the experience of Human Factors shows that these problems can be overcome, even for rather large and complex systems. The numerous methods developed by Human Factors for collecting and representing task data are ready to be used and adapted to the problems of computer interface design. The additional contributions of cognitive psychology have resulted in procedural task analyses that can help evaluate designs rapidly and efficiently. System developers thus have a powerful set of concepts and tools already available, and can anticipate even more comprehensive task analysis methods in the future.

Already developing is one set of ideas about the design of functionality, in which rather than the unsystematic choice of features which the user somehow infers how to apply, the top-level pattern of user–machine function interaction is the target of basic system design. This approach links conventional concepts of software development more directly to task analysis to enable systems that are both effective and highly usable.

Glossary

Cognitive psychology: A branch of psychology that is concerned with rigorous empirical and theoretical study of human cognition, the intellectual processes having to do with knowledge acquisition, representation, and application.

Cognitive task analysis: A task analysis that emphasizes the knowledge required for a task and its application, such as decision-making and its background knowledge.

Functionality: The set of user-accessible functions performed by a computer system; the kinds of services or computations performed that the user can invoke, control, or observe the results of.

GOMS model: A theoretical description of human procedural knowledge in terms of a set of Goals, Operators (basic actions), Methods, which are sequences of operators that accomplish goals, and Selection rules that select methods appropriate for goals. The goals and methods typically have a hierarchical structure. GOMS models can be thought of as programs that the user learns and then executes in the course of accomplishing task goals.

Human factors: Originated when psychologists were asked to tackle serious equipment design problems during World War II, this discipline is concerned with designing systems and devices so that they can be easily and effectively used by humans. Much of Human Factors is concerned

with psychological factors, but important other areas are biomechanics, anthropometrics, work physiology, and safety.

Task: This term is not very well defined, and is used differently in different contexts, even within Human Factors and HCI. Here, it refers to purposeful activities performed by users, either a general class of activities, or a specific case or type of activity.

Task domain: The set of knowledge, skills, and goals possessed by users that is specific to a kind of job or task.

Usability: The extent to which a system can be used effectively to accomplish tasks; a multidimensional attribute of a system, covering ease of learning, speed of use, resistance to user errors, intelligibility of displays, and so forth.

User interface: The portion of a computer system that the user directly interacts with, consisting not just of physical input and output devices, but also the contents of the displays, the observable behavior of the system, and the rules and procedures for controlling the system.

Further Information

The reference list contains useful sources for following up this chapter. Landauer (1995) provides excellent economic arguments on how many systems fail to be useful and usable. The most useful sources on task analysis are Kirwan and Ainsworth (1992), Diaper and Stanton (2004a), and Beevis et al. (1992). John and Kieras (1996a,b) and Kieras (1997, 2004) provide detailed overviews and methods for GOMS analysis.

Acknowledgment

The concept of high-level GOMS analysis was developed in conjunction with Ruven Brooks, of Rockwell Automation, who also provided helpful comments on the first version of this chapter.

Designing Multimedia Applications for User Experience

Alistair Sutcliffe
University of Manchester

34.1 Introduction

Multimedia is rapidly becoming the default in most applications apart from transaction processing systems where numbers and text dominate, although multimedia has also been used extensively in task-based applications for process control and safety-critical systems (Hollan et al., 1984; Alty, 1991). With the advent of the Web 2.0 and beyond, interactive multimedia is a continuing design challenge. Note the "interactive" in multimedia; this is important since the objective is not only to deliver information through a variety of media (text, speech, image, video, music, etc.), but also to engage the user in simulating and exciting interaction. The view that the user interface (UI) design goes beyond functional and usability into user experience (UX) is well established in the Human–Computer Interaction (HCI) community (Hassenzahl and Tractinsky, 2006). In this chapter, the author takes a UX-oriented view of multimedia, so interaction will be treated as one medium in the multimedia design space.

This chapter has four aims:

1. Describe the properties of media resources and how they are used in design.
2. Propose design guidelines for conveying information in multimedia.
3. Explain the concept of UX and its relationship to interactive multimedia.
4. Propose multimedia design guidelines for UX.

The first part of the chapter will cover the design process for multimedia applications; starting with an information analysis, it then progresses to deal with issues of media selection and integration. A more detailed description of the process and information modeling techniques is given in Sutcliffe (2003, 2012). Multimedia design involves several special areas that are technical subjects in their own right. For instance, design of text is the science (or art) of calligraphy that has developed new fonts over many years; visualization design encompasses the creation of images, either drawn or captured as photographs. Design of moving images, cartoons, video, and film are further specializations, as are musical composition and design of sound effects. Multimedia design lies on an interesting cultural boundary between the creative artistic community and science-based engineering. One implication of this cultural collision is that space precludes "within-media" design being dealt with in depth in this chapter, i.e., guidelines for design of one particular medium.

The second part of the chapter broadens multimedia design to cover UX and design of applications where the goal is to persuade, entertain, or educate the user. Design in this section considers interaction design, aesthetics, and emotional effects of multimedia. UX design is a complex subject, so the background to this topic will only be reviewed briefly. For a more in-depth treatment of UX design, the reader is referred to Sutcliffe (2009).

34.2 Media Properties and Design Principles

We perceive multimedia using either our visual sense (text, photographs, drawings, animations), audio (speech, music, natural and artificial sounds), or both (film with a sound track). Haptic (touch), olfactory (smell), and gustatory (taste) senses may be more important in the near future; however, for the present, visual and audio senses dominate. How we perceive and understand multimedia is limited by cognitive constraints inherent in the way our brain processes information. These are summarized as follows; more in-depth explanation of these issues is given in Sutcliffe (2012):

- Selective attention: We can only attend to one input on one sensory channel at a time. Visually, this is a consequence of the way our eyes focus on images, on only one small area at a time. For audio, we can only pick out one message from the background noise; two or more separate sounds interfere, and we have to selectively attend to one or the other. We can overcome this limitation by time-slicing our attention between different images or sounds, but at the penalty of forgetting.
- Working memory: Information from our senses is perceived rapidly, but the understanding phase encounters a very limited bottleneck, working memory. Working memory is a very limited scratch pad or cache memory containing about five facts/ideas or concepts (chunks in the psychological jargon) at any one time. As information is received, it overwrites the current content of working memory, so we can only actively process a small quantity of information at once.
- Knowledge integration: We make sense of the world by seeing or hearing patterns, and those patterns are easier to understand when we can associate them with things we already know, our memory. This allows us to overcome some of the selective attention and working memory limitations. For example, when moving images and an audio sound track are integrated in a film, we can process information on two channels without difficulty.
- Arousal and affect: Any change in images or audio automatically demands our attention (see selective attention); however, change also alerts us, and this increases our arousal. Change in multimedia is therefore more interesting and possibly exciting. Content of multimedia can connect with our emotions as we react instinctively to scary images or loud noises.

The links between different types of media and these psychological implications are summarized in Table 34.1.

The psychological implications also motivate multimedia design principles (ISO, 1997, 1998). The principles are high-level concepts, which are useful for general guidance, but they have to be interpreted

TABLE 34.1 Psychological Constraints and Implications for Multimedia Design

Medium	Selective Attention	Working Memory	Arousal and Affect
Image: Photograph	Eye scanning depends on salient features on images	No detail of image persists; only a few facts can be extracted at one time	Highlighting components increase arousal; other effects depend on content
Text	Eye scanning is set by text format and reading order	Only a few (four to five) facts can be extracted at once	Depends on content
Moving image: Film, cartoons	Attention is automatic; it is difficult to ignore dynamic media	Rapid overwriting; only high-level "gist" facts can be extracted	Dynamic media are more arousing than static media; content can be very effective in emotional reactions
Audio: Speech	Attention is automatic. Speech dominates over other sound	Rapid overwriting; only high-level "gist" facts can be extracted	Dynamic media are more arousing; content and delivery (voice tone) can be used for emotional effects
Audio: Other sounds	Attention is automatic	Facts depend on recognition, i.e., matching sound to memory	Audio has a range of arousal and emotional effects

in a context to give more specific advice. The following design principles are cross-referenced to the corresponding psychological constraints:

- *Thematic congruence*. Messages presented in different media should be linked together to form a coherent whole. This helps comprehension as the different parts of the message make sense by fitting together. Congruence is partly a matter of designing the content so that it follows a logical theme (e.g., the script or story line makes sense and does not assume too much about the user's domain knowledge), and partly a matter of attentional design to help the user follow the message thread across different media (knowledge integration, selective attention).
- *Manageable information loading*. Messages presented in multimedia should be delivered at a pace that is either under the user's control or at a rate that allows for effective assimilation of information without causing fatigue. The rate of information delivery depends on the quantity and complexity of information, the effectiveness of the design in helping the user extract the message from the media, and the user's domain knowledge and motivation. Some ways of reducing information overload are to avoid excessive use of concurrent dynamic media and give the user time to assimilate complex messages. This guards against overloading user's working memory. Since our working memory has a small capacity and gets continually overwritten by new input, controlling the pace and quantity of input can reduce overloading.
- *Compatibility with the user's understanding*. Media should be selected that convey the content in a manner compatible with the user's existing knowledge, for example, the radiation symbol and road sign icons are used to convey hazards and dangers to users who have the appropriate knowledge and cultural background. The user's ability to understand the message is important for designed image media (diagrams, graphs) when interpretation is dependent on the user's knowledge and background (knowledge integration).
- *Complementary viewpoints*. Similar aspects of the same subject matter should be presented on different media to create an integrated whole. Showing different aspects of the same object, for example, a picture and a design diagram of a ship, can help memorization by developing richer schema and better memory cues (knowledge integration).

- *Consistency*. It helps users learn an interface by making the controls, command names, and layout follow a familiar pattern. People recognize patterns automatically, so operating the interface becomes an automatic skill. Consistent use of media to deliver messages of a specific type can help by cueing users with what to expect (selective attention, knowledge integration).
- *Interaction and engagement*. These help understanding and learning by encouraging the user to solve problems. Memory is an active process. Interaction increases arousal, and this makes the user's experience more vivid, exciting, and memorable (arousal and affect).
- *Reinforce messages*. Redundant communication of the same message on different media can help learning. Presentation of the same or similar aspects of a message helps memorization by the frequency effect. Exposing users to the same thing in a different modality also promotes rich memory cues (knowledge integration; see also complementary viewpoints).

Many of the principles are motivated by knowledge integration, which is one of the reasons for the "multi" in multimedia.

The following section provides some guidelines to address these issues.

34.3 Media Selection and Combination

Designers have to solve two problems:

1. Which media resources to select (or create) to convey information?
2. How to integrate media resources to convey information more effectively and improve UX?

Media resources may be classified as either static (do not change, e.g., text, images) or dynamic in the sense that they change during presentation (e.g., speech, all audio media, moving image media such as films, cartoons). Another distinction is also useful: realistic/not realistic, reflecting the designer's involvement in creating the medium. For instance, a photograph or video may capture an image of the real world; alternatively, the hand of the designer may be more overt in drawings, sketches, and diagrams. Note that it is the content that determines the media resource rather than the presentation medium; for example, a diagram is still a diagram whether it has been photographed or drawn on paper and scanned. The design of media resources is important, because abstract concepts can only be conveyed by language (text/speech), designed audio (music), or by designed images (diagrams, cartoons). More fine-grained taxonomic distinctions can be made, for instance, between different signs and symbolic languages (see Bernsen, 1994), but richer taxonomies increase specification effort. Media resources can be classified using the three criteria in the decision tree illustrated in Figure 34.1.

The approach to classifying media uses a decision tree "walkthrough" with the following questions that reflect the facets of the classification:

- Is the medium perceived to be realistic or not? Media resources captured directly from the real world will usually be realistic, for example, photographs of landscapes, sound recordings of bird song, etc. In contrast, nonrealistic media are created by human action. However, the boundary case category that illustrates the dimension is a realistic painting of a landscape.
- Does the medium change over time or not? The boundary case here is the rate of change, particularly in animations where some people might judge 10 frames/s to be a video but 5 slides in a minute shown by a PowerPoint presentation to be a sequence of static images.
- Which modality does the resource belong to? Most media are visual (image/text) or audio (music/speech), although one resource may exhibit two modalities. For example, a film with a sound track communicates in both visual and audio modalities.

The walkthrough process informs selecting appropriate media resources to convey information content. Information content may be apparent from the resources provided, such as diagrams, text, etc; however, in some cases, only high-level user requirements may be given, such as "present

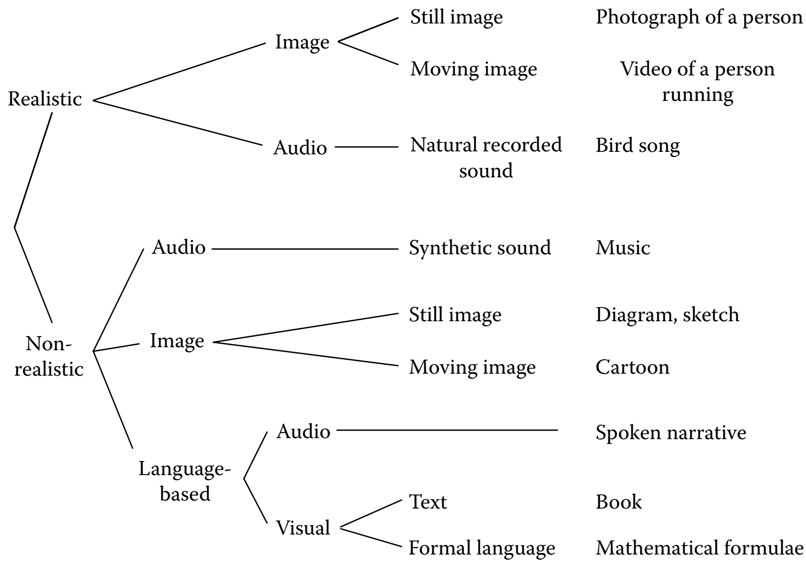

FIGURE 34.1 Decision tree for classifying media resources.

information to influence people to adopt a healthy diet, give up smoking, or purchase a product from an e-commerce website." The designers will have to source the content if it is not provided, and then further media resources may have to be designed to amplify the message. For example, education materials to explain the working of a car engine may be simple diagrams and text. To really convey how an engine works requires an interactive animation so the student can see the sequence of movements and relate these to a causal model of the internal combustion engine. Multimedia design, therefore, often involves transforming and augmenting information content for effective communication.

Recommendations for selecting media have to be interpreted according to the users' task and design goals. If information provision is the main design goal, for example, in a tourist kiosk information system, then persistence of information and drawing attention to specific items is not necessarily as critical as in tutorial applications. Task and user characteristics influence media choice; for instance, verbal media are more appropriate to language-based and logical reasoning tasks; visual media are suitable for spatial tasks involving moving, positioning, and orienting objects. Some users may prefer visual media, while image is of little use for blind users.

34.3.1 Information Architecture

This activity consists of several activities, which will differ according to the type of application. Some applications might have a strong task model; for instance, a multimedia process control application where the tasks are monitoring a chemical plant, diagnosing problems, and supporting the operator in controlling plant operation. In goal-driven applications, information requirements are derived from the task model. In information provision applications such as websites with an informative role, information analysis involves categorization, and the architecture generally follows a hierarchical model. In the third class of explanatory or thematic applications, analysis is concerned with the story or argument, that is, how the information should be explained or delivered. Educational multimedia and websites with persuasive missions fall into the last category.

In information-provision applications, classification of the content according to one or more user views defines the information architecture; for example, most university departments have an information structure with upper-level categories for research, undergraduate courses, postgraduate courses, staff interests, departmental organization, mission, and objectives. For explanatory applications,

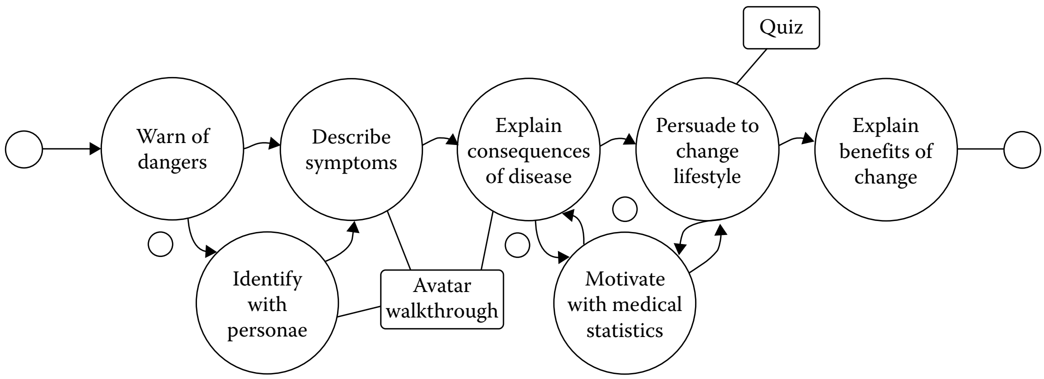

FIGURE 34.2 Thematic map for a healthcare promotion application.

a theme or story line needs to be developed. This will depend on the application's objectives and the message the owner wishes to deliver. A thematic map from a health awareness application is illustrated in Figure 34.2.

In the case described in Figure 34.2, the requirement is to convince people of the dangers of heart disease. The theme is a persuasive argument that first tries to convince people of the dangers from smoking, poor diet, stressful lifestyles, etc. It then explains how to improve their lifestyle to prevent heart disease, followed by reinforcing the message with the benefits of a healthy lifestyle such as lower health insurance, saving money, longer life, etc. Subthemes are embedded at different points, so users can explore the facts behind heart disease, the statistics and their exposure, how to get help, etc. Information is then gathered for each node in the thematic map. How this architecture will be delivered depends on interaction design decisions: it could, for example, become an interactive story to explore different lifestyle choices, combined with a quiz. The outcome of information architecture analysis will be an information-enhanced task model, a thematic map, or a hierarchy/network to show the structure and relationships of information categories. The next step is to analyze the information content by classifying it by types.

Information types are amodal, conceptual descriptions of information components that elaborate the content definition. Information components are classified into one or more of the following:

- Physical items relating to tangible observable aspects of the world
- Spatial items relating to geography and location in the world
- Conceptual abstract information, facts, and concepts related to language
- Static information that does not change: objects, entities, relationships, states, and attributes
- Dynamic, or time-varying information: events, actions, activities, procedures, and movements
- Descriptive information, attributes of objects, and entities
- Values and numbers
- Causal explanations

Information is often complex or composite, so one component may be classified with more than one type; for instance, instructions on how to get to the railway station may contain procedural information (the instructions "turn left, straight ahead," etc.), and spatial or descriptive information (the station is in the corner of the square, painted blue). The information types are "tools for thought," which can be used either to classify specifications of content or to consider what content may be necessary. To illustrate, for the task "navigate to the railway station," the content may be minimally specified as "instructions how to get there," in which case the information types prompt questions in the form "what sort of information does the user need to fulfill the task/user goal?" Alternatively, the content may be specified as a scenario narrative of directions, waymarks to recognize, and description of the target. In this case, the types

classify components in the narrative to elucidate the deeper structure of the content. The granularity of components is a matter of the designer's choice and will depend on the level of detail demanded by the application. To illustrate the analysis:

Communication goal: Explain how to assemble a bookshelf from ready-made parts.

Information component 1:

Parts of the bookshelf, sides, back, shelves, connecting screws

Mapping to information types:
Physical-Static-Descriptive: parts of the bookshelf are tangible, do not change, and need to be described
Physical-Static-Spatial: dimensions of the parts, the way they are organized
Physical-Static-Relationship: this type could also be added to describe which parts fit together

Information component 2:

How to assemble parts instructions?

Mapping to information types:
Physical-Dynamic-Discrete action (each step in the assembly)
Physical-Dynamic-Procedure (all the steps so the overall sequence is clear)
Physical-Static-State (to show final assembled bookshelf)

The mapping physical information at the action and then the procedure level is to improve integration of information and hence understanding, following the "reinforce messages" principle. First, each step is shown, then the steps in a complete sequence (the procedure), and finally the end state of the completed assembly.

34.3.2 Matching Information to Media

The following heuristics are supplemented by more detailed examples in Sutcliffe (2012) and ISO (1998).

- To convey detail, use static media, for example, text for language-based content, diagrams for models, or still image for physical detail of objects (Booher, 1975; Faraday and Sutcliffe, 1998).
- To engage the user and draw attention, use dynamic media, for example, video for physical information, animation, or speech.
- For spatial information, use diagrams, maps, with photographic images to illustrate detail and animations to indicate pathways (Bieger and Glock, 1984; May and Barnard, 1995).
- For values and quantitative information, use charts and graphs for overviews and trends, supplemented by tables for detail (Bertin, 1983; Tufte, 1997).
- Abstract concepts, relationships, and models should be illustrated with diagrams explained by text captions and speech to give supplementary information.
- Complex actions and procedures should be illustrated as a slideshow of images for each step, followed by a video of the whole sequence to integrate the steps. Text captions on the still images and speech commentary provide supplementary information (Hegarty and Just, 1993). Text and bullet points summarize the steps at the end, so choice trade-offs may be constrained by cost and quality considerations.
- To explain causality, still and moving image media need to be combined with text (Narayanan and Hegarty, 1998), for example, the cause of a flood is explained by text describing excessive rainfall with an animation of the river level rising and overflowing its banks. Causal explanations of physical phenomena may be given by introducing the topic using linguistic media, showing cause and effect by a combination of still image and text with speech captions for commentary; integrate the message by moving image with voice commentary and provide a bullet point text summary.

34.4 UX and Multimedia

The term User EXperience (UX) grew out of concerns that traditional concepts of usability (ISO, 1997; Shneiderman and Plaisant, 2004) did not cover the more aesthetic aspects of design. Traditionally, usability has emphasized ease of use, ease of learning, and effective operation, in other words, the "drivability of an interface," and how well it fits the user's tasks and goals. Norman (2004) questioned the traditional view of usability in his book on emotion in design and pointed to the importance of aesthetic aspects in UIs and users' emotional responses to well-designed products. Researchers in HCI began to question how aesthetic design might be related to usability, led by the pioneering studies of Tractinsky (1997) and Lavie and Tractinsky (2004) who experimentally manipulated usability and aesthetic qualities of a design to coin the now well-known aphorism "what is beautiful is usable."

UX also evolved from marketing concepts such as "consumer experience" (Thomas and Macredie, 2002), which refers to the totality of product experience including sales, setup, use, support during use, and maintenance. Other influences came from research into enjoyment and fun (Blythe et al., 2004) and application areas such as games and entertainment where traditional usability appeared to be less appropriate. When excitement and amusement are the major design goals, interaction, metaphor, and aesthetics become important concerns. Hence, UX generally refers to a wider concept of design beyond functional products, which encompasses interaction, flow (Csikszentmihalyi, 2002), and aesthetic design. The content of media as well as the design of interaction in multimedia systems contribute to UX.

The criteria which may influence UX, and hence user satisfaction and use of IT products, are summarized in Figure 34.3.

Content and functionality are related to users' goals or requirements, so this aspect is dealt with in processes for requirement analysis (Sutcliffe et al., 2006) and user-centered design. Multimedia represents content to improve UX compared to monomedia (e.g., text or image alone) and is used to implement interaction using graphical metaphors, characters, speech, and audio. Content and services are closely related to task goals, so these criteria will be more important in work-related applications. In contrast, engagement and aesthetics may gain importance in entertainment and leisure applications.

Customization interacts with content and services since users are rarely a homogenous group, and different subgroups often require subsets of the overall content and functions. Customization may be at the subgroup or individual level (personalization), to increase the fit between the application and the user's needs, which, in turn, increases the user's commitment to a design. UX is enhanced not only through more stimulating interaction and better fit to the user's task and abilities (Sutcliffe et al., 2005), but also through the sense of ownership. Personalizing the choice of media and content within images, videos, etc. are examples of customization.

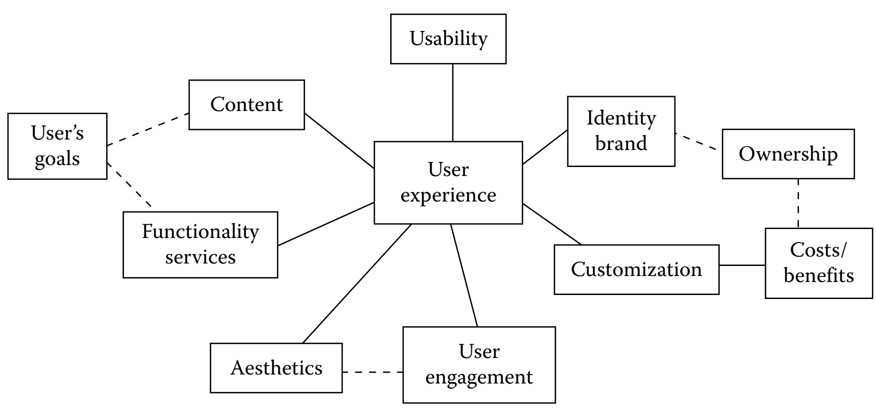

FIGURE 34.3 Components of UX.

Brand and identity interact with content and the users' background. If users are familiar with product brands, they are naturally going to be well disposed toward an application. Similarly, familiar content can be motivating as it is easier to assimilate. However, the users' reaction to content is complex; in some domains, for example, education and entertainment, challenging and unfamiliar content may be at a premium for stimulating learning and excitement, while in traditional information processing, familiar patterns of content make task performance more effective. At a high level, content and the tone of its expression in language may be familiar or not in a cultural sense, for example, the expression of material in English, American English, or the user's native language in international UIs.

Usability is always important, but the degree of ease of use may depend on the domain, varying between high-quality usability when content and functionality are priorities, to sufficient usability when user engagement and fun are the main criteria. Aesthetics or the "look and feel" of a multimedia application may be important in domains where design quality and brand image are at a premium (especially on websites). The debate about the relative influence of aesthetics is complex, where aesthetics is often restricted to the perception or "look" of a UI, separate from interaction or the "feel" of users' interfaces, which focuses on making interaction exciting and motivating for the user while also delivering effective content, and functionality that meets the users' goals.

34.5 Components of User Engagement

User engagement synthesizes several influences to promote a sense of flow and fluid interaction leading to satisfying arousal and pleasurable emotions of curiosity, surprise, and joy. The contributing influences are summarized in Figure 34.4.

The three main components of user engagement are *interaction*, *multimedia*, and *presence*. Interaction describes how the user controls the computer. The default is standard WIMP (windows, icons, mouse, pointer) interaction on graphical UIs. Multimedia not only deals with the representation of content, but also the interactive environment and how the user and the means of interaction are represented, ranging from simple cursors to icons and interactive avatars with fly-through interactive paradigms. Presence is determined by the representation of the user, which ranges from a cursor in a 2D interactive surface to an avatar in a more elaborate 3D interactive world. Presence is also related to, and augmented by, interaction. Acting in a 3D world and interaction with objects all increase the sense of "being there" and arousal. Flow is the key concept for understanding interaction in terms of the pace of action, complexity of actions, and the rate of change.

Flow, presence, and immersion are concepts which influence the choice of media for interaction; so in this case it is UI rather than content which is the subject of multimedia design. Text dominates

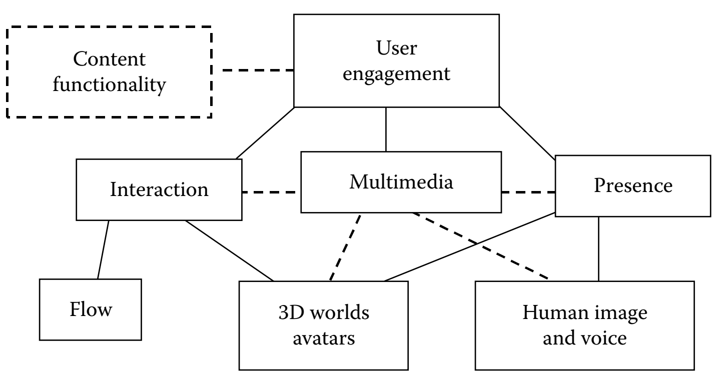

FIGURE 34.4 Issues related to user engagement and multimedia.

traditional form-filling and menu interfaces, although graphics in the form of icons and structures (windows, sliders, menu bars) are now standard UI components. In the emerging and future UIs, new media will appear, as the user interacts not just via a cursor but also through an avatar, situated in a graphical virtual world, occupied by animated objects, with speech and audio. Multimedia interaction improves UX through flow, presence, and immersion.

34.5.1 Interaction and Flow

Flow is a finely tuned balancing act between the user's abilities and skills, and the challenges provided by learning new interactions, and then responding to events. It is the sense of engagement and being absorbed in an interactive experience. The concept involves optimal arousal produced by a "sweet spot" trade-off between challenge and difficulty on one hand and ease of operation and achievement on the other. If operating a UI is too difficult, users will get frustrated and discouraged and may give up, leaving them with negative emotions and adverse memory of the experience. In contrast, if operating the UI is too easy, they become bored, excitement (or arousal) decreases, and they turn their attention to more interesting things. The trick is to keep interaction in the flow zone (see Figure 34.5), an intuition appreciated by game designers. Games need to maintain the pace of change with unpredictable events, while not overwhelming the user with too much change that exceeds their capabilities. They rapidly become used to patterns of events leading to decreased arousal as the unfamiliar becomes familiar.

34.5.2 Presence

The origins of presence are in virtual reality (VR), in which the user is represented by an avatar or virtual character. The avatar places the user inside a 3D graphic world, so interaction becomes very different from operating an interface through a cursor. Presence is the sense of "being there" inside a virtual world as a representation of oneself (embodied or immersed interaction). Embodied interaction is more complex than standard 2D interfaces, since the user can control movement directly, manipulate objects in an almost natural manner, and even feel objects if haptic feedback is provided. The sense of immersion and control is enhanced via natural movement. Virtual worlds become engaging because they invoke curiosity and arousal. Interaction becomes transparent, i.e., the user is not aware of the computer, instead feeling immersed and becoming absorbed in the virtual graphical world (see Figure 34.6).

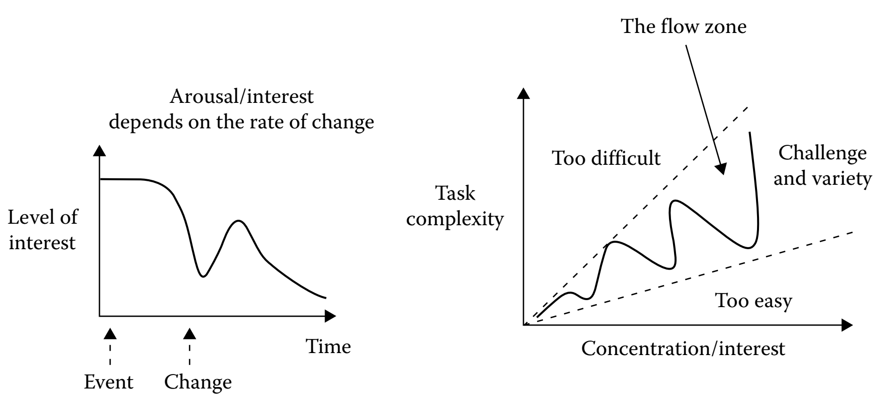

FIGURE 34.5 Change in arousal as events become familiar. The concept of flow.

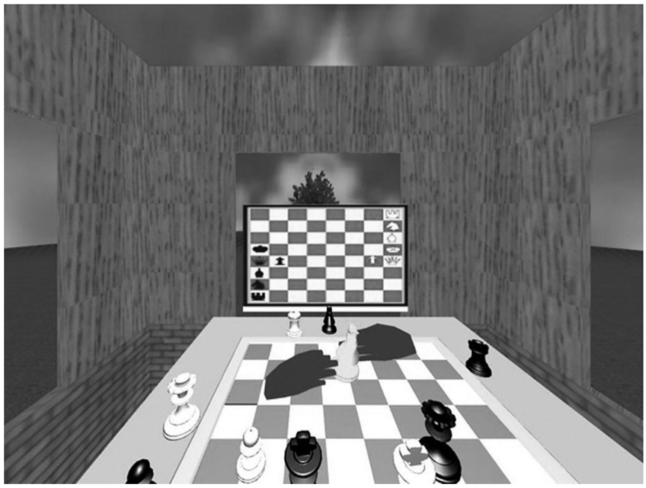

FIGURE 34.6 Virtual world illustrating the user's presence represented as two virtual hands.

34.5.3 Engagement and Social Presence

Social presence theory (Short et al., 1976) argues that different communication channels and representations promote more or less sense of social presence, i.e., awareness of the identity, location, and personalities of other people. The theory does not give a formal classification or model of social presence; although it can be reinterpreted in terms of a model of communication which describes degradations from the ideal of face-to-face, colocated communication. E-mail is the least engaging since the time gap between turns destroys the sense of a dialog, whereas instant messaging (IM) approaches synchronous exchange and becomes more engaging. In IM, the pace of exchange approaches a conversation, and the sense of presence increases. Adding video or even still images improves presence by providing more information about the other person (see Figure 34.7). Contextual information gives us the background to an ongoing conversation. The context may be provided by a user profile, a room or whatever has been constructed in the virtual world for interpreting the conversation.

FIGURE 34.7 *SecondLife*, illustrating avatars that represent the characters people adopt and the location with others, both of which promote social presence.

Strange as it may seem, it takes very little to create an illusion of presence. Our powerful imaginations just need a few hints (priming or framing effects in psychology) to conjure up a perceived reality, as Pinter* and other proponents of minimalist theater have demonstrated. In a series of experiments, Reeves and Nass (1996) showed how we treat computer-based media as if they corresponded to real people. Their computer as social actor (CSA) paradigm explains how we treat computers as virtual people even when we are presented with limited cues, such as a photograph of a person or human voice. Indeed, the image can be artificial, cartoon-like, with little correspondence to reality; the same applies to the voice. Chatterbots, avatars on the web equipped with simple semi-intelligent scripts for responding to human conversations, are treated like real characters, and some people actually form relationships with these virtual characters (De Angeli and Brahnam, 2008).

34.6 Media Design for User Engagement

Multimedia design is frequently motivated by the need to attract users' attention and to make the UX interesting and engaging. These considerations may contradict some of the earlier guidelines, because the design objective is to please users and capture their attention rather than deliver information effectively. First, a health warning should be noted: the old saying "beauty is in the eye of the beholder" has a good foundation. Judgments of aesthetic quality suffer from considerable individual differences. A person's reaction to a design is a function of their motivation (Brave and Nass, 2008), individual preferences, knowledge of the domain, and exposure to similar examples, to say nothing of peer opinion and fashion.

In human–human conversation, we modify our reactions according to our knowledge (or assumptions) about the other person's role, group identification, culture, and intention (Clark, 1996). For example, reactions to a military mannequin will be very different from those to the representation of a person. Male voices tend to be treated as more authoritative than female voices. Simple photographs or more complex interactive animations (talking heads or full body mannequins) have an attractive effect; however, the effectiveness of media representing people depends on the characters' appearance and voice (see Figure 34.8).

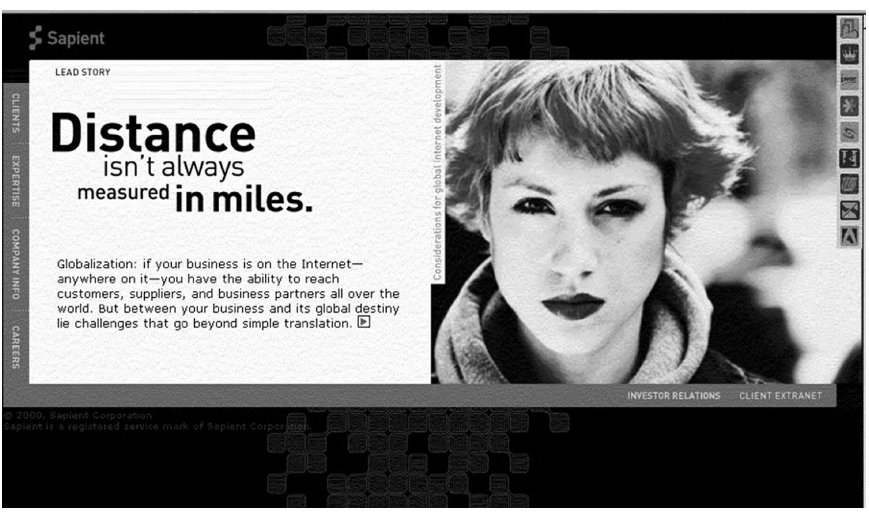

FIGURE 34.8 Effective use of human image for attraction. The picture attracts by the direction of gaze to the user as well as by the appearance of the individual.

* http://en.wikipedia.org/wiki/Harold_Pinter

Use of human-like forms is feasible with prerecorded videos and photographs; however, the need depends on the application. Video representation of the lecturer can augment presentations, and video communication helps interactive dialog. A good speaker holds our attention by a variety of tricks, such as maintaining eye contact, varying the voice tone, using simple and concise language, as well as delivering an interesting message. These general effects can be reinforced by projected personality. Friendly people are preferred over colder, more hostile individuals. TV announcers who tend to be middle-aged, confident, but avuncular characters have the attention-drawing power of a dominant yet friendly personality. Both sexes pay attention to extrovert, young personalities, while the male preference for beautiful young women is a particularly strong effect. These traits have long been exploited by advertisers. There are lessons here for multimedia designers as the web and interactive TV converge, and when we want media to convey a persuasive message (Reeves and Nass, 1996; Fogg et al., 2008). Media selection guidelines for motivation and persuasion, adapted from Reeves and Nass (1996), can be summarized as follows:

- Human image and speech invokes the CSA effect to facilitate motivation and persuasion.
- Photographs of people attract attention especially when the person is looking directly at the user.
- Faces that represent the norm in a population (Mr./Ms. Average) and young children are more attractive. We are very susceptible to the large-eyes effect in young animals, as exploited by Disney cartoons.
- Polite praise: Use of please, thank you, and simple compliments such as "that was an excellent choice" increase people's tendency to judge the computer as pleasant and enjoyable.
- Short compelling argument such as the well-known British World War I recruiting poster featuring General Kitchener gazing directly at the viewer with the caption "your country needs you."

34.6.1 Media for Emotional Effects

Media design for affect (emotional response and arousal) involves both choice of content and interaction. Arousal is increased by interactive applications, surprising events during interaction, use of dynamic media, and challenging images. In contrast, if the objective is to calm the users, arousal can be decreased by choice of natural images and sounds, and soothing music. The most common emotional responses that designers may want to invoke are pleasure, anxiety and fear, and surprise. Pleasure, anxiety, and fear usually depend on our memory of agents, objects, and events (Ortony et al., 1988), so content selection is the important determinant. Anxiety can be evoked by uncertainty in interaction and cues to hidden effects, while emotional response of fear or pleasure will depend on matching content to the user's previous experience. Some guidelines to consider are as follows:

- *Dynamic media*, especially video, have an arousing effect and attract attention; hence, video and animation are useful in improving the attractiveness of presentations. However, animation must be used with care as gratuitous video that cannot be turned off quickly offends (Spool et al., 1999).
- *Speech* engages attention because we naturally listen to conversation. Choice of voice depends on the application: female voices for more restful and information effects, male voices to suggest authority and respect (Reeves and Nass, 1996).
- *Images* may be selected for mood setting, for example, to provide a restful setting for more important foreground information (Mullet and Sano, 1995). Backgrounds in half shades and low saturation color provide more depth and interest in an image.
- *Music* has an important emotive appeal, but it needs to be used with care. Classical music may be counterproductive for a younger audience, while older listeners will not find heavy metal pop attractive. Music can set the appropriate mood, for example, loud strident pieces arouse and excite, whereas romantic music calms and invokes pleasure, etc.
- *Natural sounds* such as running water, wind in trees, bird song, and waves on a seashore have restful properties and hence decrease arousal.

- *Dangerous and threatening episodes*, for example, being chased by a tiger, gory images (mutilated body), and erotic content all increase arousal and invoke emotions ranging from fear to anger, whereas pleasant images (e.g., flowers, sunset) tend to decrease it, having calming effects and producing pleasurable emotional responses.
- *Characters* can appear threatening or benevolent depending on their appearance or dress. For example, disfigured people appear threatening and evoke emotions ranging from fear to disgust. Characters familiar from popular culture can be used for emotional effect.
- *Spoken dialog* is probably the most powerful tool for creating emotional responses, from threats to empathy. Emotional effects are additive; so choice of character with a threatening appearance, complemented by a menacing voice tone and an aggressive dialog, all reinforce the emotions of anxiety and fear.

Media integration rules may be broken for emotive effects. For example, use of two concurrent video streams might be arousing for a younger audience, as Music TV (MTV) and pop videos indicate. Multiple audio and speech tracks can give the impression of complex, busy, and interesting environments.

34.6.2 Multimedia and Aesthetic Design

Judging when aesthetics may be important will be set by the design goals of the owner of the application. For example, in e-commerce applications with high-value, designer-label products, aesthetic presentation is advisable; similarly, when selling to a design-oriented audience. Aesthetic design primarily concerns graphics and visual media. Evaluation questionnaires can assess aesthetics and more creative aspects of visual design (Lavie and Tractinsky, 2004); however, these measure user reaction to general qualities, such as "original," "fascinating," "clear," and "pleasant." The following heuristics provide more design-directed guidance, but they may also be employed for evaluation (Sutcliffe, 2002; Sutcliffe and De Angeli, 2005).

- *Judicious use of color*: Color use should be balanced, and low saturation pastel colors should be used for backgrounds. Designs should not use more than two to three fully saturated intense colors. Yellow is salient for alerting, red/green have danger/safety positive/negative associations, and blue is more effective for background. Low-saturated colors (pale shades with white) have a calming effect and are also useful for backgrounds. Color is a complex subject in its own right; for more guidance, refer to Travis (1991).
- *Depth of field*: Use of layers in an image stimulates interest and can attract by promoting curiosity. Use of background image with low-saturated colors provides depth for foreground components. Use of layers in an image and washed-out background images stimulate curiosity and can be attractive by promoting a peaceful effect.
- *Use of shape*: Curved shapes convey an attractive visual style, in contrast to blocks and rectangles that portray structure, categories, and order in a layout.
- *Symmetry*: Symmetrical layouts, for example, bilateral, radial organization, can be folded over to show the symmetrical match.
- *Simplicity and space*: Uncluttered, simple layouts that use space to separate and emphasize key components.
- *Design of unusual or challenging images* that stimulate the users' imagination and increase attraction; unusual images often disobey normal laws of form and perspective.
- *Visual structure and organization*: Dividing an image into thirds (Right, Center, Left; or Top, Middle, Bottom) provides an attractive visual organization, while rectangular shapes following the golden ratio (height/width = 1.618) are aesthetically pleasing. Use of grids to structure image components promotes consistency between pages.

Although guidelines provide ideas that can improve aesthetic design and attractiveness of interfaces, there is no guarantee that these effects will be achieved. Design is often a trade-off between ease of use

and aesthetic design; for instance, use of progressive disclosure to promote flow may well be perceived by others as being difficult to learn. Visual effects often show considerable individual differences and learning effects; so, a well-intentioned design might not be successful. The advice, as with most design, is to test ideas and preliminary designs with users to check interpretations, critique ideas, and evaluate their acceptability. There are several sources of more detailed advice on aesthetics and visual design (Mullet and Sano, 1993; Kristof and Satran, 1995; Lidwell et al., 2003).

34.6.3 Metaphors and Interaction Design

While task and domain analysis can provide ideas for interaction design, this is also a creative process. Interaction design is essentially a set of choices along a dimension from simple controls, such as menus and buttons where the user is aware of the interface, to embodiment in which the user becomes involved as part of the action by controlling an avatar or other representation of their presence. At this end of the dimension, multimedia interaction converges with virtual reality. Interactive metaphors occupy the middle ground.

Some interactive metaphors are generally applicable, such as timelines to move through historical information, the use of a compass to control the direction of movement in an interactive space, controls based on automobiles (steering wheels) or ships (rudders). Others will be more specific, for example, selecting and interacting with different characters (young, old, male, female, overweight, fit, etc.) in a health-promotion application. Design of interaction also involves creating the microworld within which the user moves and interactive objects that can be selected and manipulated.

Interaction via characters and avatars can increase the user's sense of engagement first by selecting or even constructing the character. In character-based interaction, the user can either see the world from an egocentric viewpoint, i.e., from their character's position, or exocentric when they see their character in the graphical world. Engagement[*] is also promoted by surprise and unexpected effects; so, as the user moves into a particular area, a new subworld opens up, or system-controlled avatars appear. These techniques are well known to games programmers; however, they are also applicable to other genres of multimedia applications. The design concepts for engagement can be summarized as follows (see Sutcliffe, 2009, for more detail):

- *Character-driven interaction*: It provides the user with a choice of avatars or personae they can adopt as representations of themselves within the interactive virtual world (see Figure 34.6). Avatar development tools enable virtual characters to be designed and scripted with actions and simple speech dialogs. Most sophisticated, semi-intelligent "chatterbots" (e.g., Alice http://alice.pandorabots.com/& Jabberwacky http://www.jabberwacky.com/) use response-planning rules to analyze user input and generate naturally sounding output; however, it is easy to fool these systems with complex natural language input.
- *Tool-based interaction*: This places the tools in the world which users can pick up; the tool becomes the interface, for example, a virtual mirror magnifies, a virtual helicopter flies (Tan et al., 2001).
- *Collaborative characters*: In computer-mediated communication, these characters may represent other users; in other applications, system-controlled avatars appear to explain, guide, or warn the user.
- *Surprise effects*: Although conventional HCI guidelines should encourage making the affordances and presence of interactive objects explicit, when designing for engagement, hiding and surprise are important.

Interaction design for an explanatory/tutorial application is illustrated in Figure 34.9. This is an interactive microworld in which the user plays the role of a dinosaur character, illustrating the use of the engagement concepts. A compass navigation metaphor allows the user to act as a dinosaur moving around the landscape, as illustrated in the figure. The user is given feedback on the characteristics of other predators and prey in the vicinity, and has to decide whether to attack or avoid them.

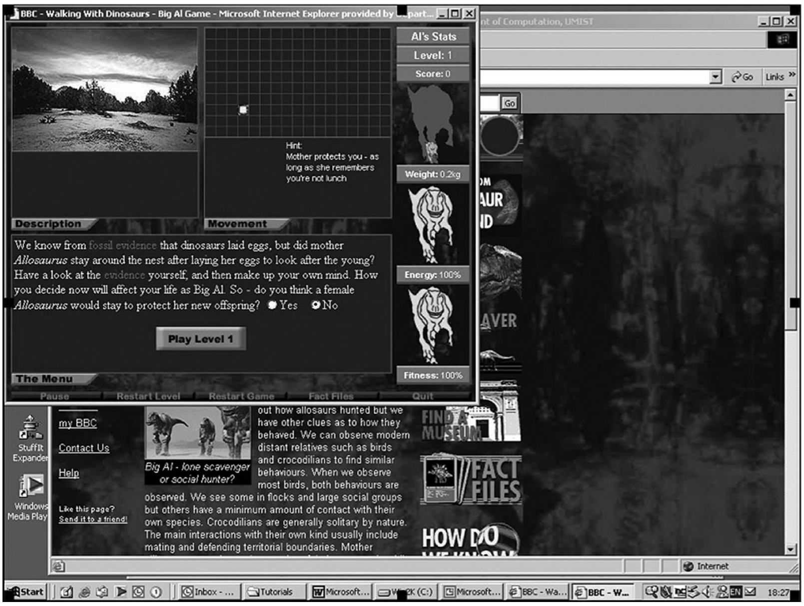

FIGURE 34.9 Interactive microworld: Big Al game (http://www.bbc.co.uk/sn/). The user plays the dinosaur role by navigating with the compass metaphor. The photograph updates with each move and the user is given a choice of attacking or avoiding other dinosaurs in the virtual world.

Other controls that might be added to such interactive microworlds could be the settings to change the environment, for example, add more predators, change the weather, etc.

34.7 A Brief Example

A healthcare example illustrates the use of some of the UX-multimedia guidelines. The objective is to persuade people through a web application to adopt healthy diets to tackle the obesity problems. Current designs (e.g., http://www.nhs.uk/livewell/; http://www.nhs.uk/Change4Life) use image and text with limited video to provide advice on the types of food to eat, what to avoid, portion size, etc. However, interactive functions are limited to simple quizzes on diet choices, which are analyzed to show the calories consumed. More adventurous designs might employ an interactive "day in your life" metaphor, where the user controls an avatar while progressing through a typical day making lifestyle choices about exercise (e.g., walk to work or drive), what to eat for each meal, choice of portion sizes, etc. The interactive game-style application provides feedback on choices, approving sensible ones or disapproving poor ones. The CSA guidelines would suggest feedback with praise for good choices given by a sympathetic character. Long-term tracking of diet and weight loss or gain could employ emotional effects to encourage (empathy, praise, empowerment), and to admonish poor progress with warnings about the dangers of obesity. The potential for multimedia design can be seen in the increasing number of mobile applications which use interactive games–style interaction with monitoring to encourage fitness.

34.8 Conclusions

Multimedia still poses many issues for further research. The design method described in this chapter coupled with user-centered design can improve quality; however, there is still a need for experts to create specific media resources, for example, film/video, audio. Furthermore, considerable research is

still necessary before we fully understand the psychology of multimedia interaction. Design for UX in multimedia is still poorly understood, for example, some people prefer avatars and rich graphical metaphors, while others find graphical interfaces annoying and prefer simpler designs. Although guidelines can improve design with advice that is based on psychological knowledge, the reaction to designs often depends on the individual; so, one-size-fits-all solutions will not work for everyone. As with most design, testing with users is always advisable, and where possible personalizing and customizing designs for the user or giving them the choice can improve the UX.

Current research frontiers are unpacking the role of interactivity in UX, as multimedia converges with VR and 3D interactive worlds, such as Google street view technology, become commonplace. Immersion and presence increase user engagement with games (Jennet et al., 2009); however, application of virtual worlds to other domains, such as education, does not always improve UX (Sutcliffe and Alrayes, 2012). Although interactive features do appear to have a positive appeal in many websites (Cry et al., 2009), the debate continues about the relative importance of interactive and aesthetic design on overall UX (Bargas-Avila and Hornbæk, 2011; Lindgaard et al., 2011). On balance, it appears that "pragmatic" design considerations such as functionality and usability outweigh "hedonic" factors such as aesthetics (Diefenbach and Hassenhalz, 2009), but the contribution of interaction design remains unclear.

In the future, language and multimodal communication will change our conception of multimedia from its current CD-ROM or web-based form into interfaces that are conversational and multisensory. Multimedia will become part of wearable and ubiquitous UIs where the media is part of our everyday environment. Design for multisensory communication will treat media and artifacts (e.g., our desks, clothes, walls in our homes) as a continuum, while managing the diverse inputs to multimedia from creative design, technology, and usability engineering will be one of the many interesting future challenges.

Applying International Usability Standards

Tom Stewart
System Concepts

35.1 Introduction

Usability has become recognized as a major factor in determining the acceptance of information systems. Poor usability has been identified as a significant cause of system failure—from large-scale government systems to small bespoke developments. The expanding use of information technology in all types of consumer products from music players and mobile phones to websites and washing machines has brought usability into even sharper focus.

In the past, poor usability was either ignored or blamed on lack of user training. The video cassette recorder (VCR) was one of the most recognizable unusable consumer products employing information technology (albeit relative simple timer technology). The number of such products with clocks "flashing 1200" after a power failure was testament to the difficulty of making a simple change to the clock setting. This in itself did not, however, appear to reduce VCR sales or adoption significantly, and customers only discovered the problems when they had already bought the machines. So, few manufacturers bothered to invest in usability.

The growth of the World Wide Web changed the information technology scene dramatically. Generally, users are offered so much choice (too much to understand properly, some might argue) that they no longer tolerate poor usability. For online retailers, their competitors are "simply a click away," and few would now launch a website without some user testing. Similarly, the mobile phone industry has recognized that the wide availability of competing products means that good usability design pays dividends. Many with a technical background find Apple products frustrating because they build a

layer between the user and technology. The limitations are not technical but commercial. This so-called walled garden approach means that Apple can control almost all aspects of the user interface and the experience of the user. For many users, this seamless (albeit restricted) interaction not only highly satisfies but also apparently justifies a significant premium on price.

Apple has long made strong claims about the "intuitiveness" of its user interfaces. Watching young children quickly use pinch and swipe on an iPad, it is hard to argue. However, the computer operating system (OS) is a different matter. Some of the ideas of point and click and direct manipulation are indeed relatively natural to many people, but such concepts as dragging a floppy disk icon to the "trash can" to eject it are far from natural. Where Apple has been successful with its limited and close system is policing a consistent look and feel on its interfaces (even as these have developed).

As an organization, they have been able to retain the control over their part of the industry which no one else has achieved. However, they are not alone in trying to ensure that users can actually use their systems and can achieve results effectively, efficiently, and even find the process satisfying. There are international usability standards that any developer or user organization can use to make their systems usable. By usable, we mean effective, efficient, and satisfying (the definition of usability in one of the international standards ISO 9241-11: 1998 Guidance on usability). ISO/TC159/SC4 is the subcommittee (SC) that deals with human–system interaction.

These standards have been developed over nearly 30 years with new and updated standards being published continuously. The purpose of this chapter is to describe how to apply international usability standards to improve the design of user interfaces and the experience of the users of information systems and technology.

Before describing the standards in detail and their impact on practice, it is important to understand the underlying principles of standardization, especially international standardization.

35.2 Underlying Principles

International standards (ISs) are powerful tools for improving the quality, effectiveness, and safety of goods and services; they are also the facilitators of world trade. International usability standards play an important role in information systems and information technology as they encompass widely accepted best practices. However, one of the most common problems people experience when trying to use these standards (and usability standards in particular) is that they do not understand the limitations and constraints that apply to the standards development (Smith 1986; Potonak 1988; Stewart 2000). This section describes the principles underlying ISs in general and international usability standards in particular.

35.2.1 Purpose of Standards

There are two main purposes for standards. First, an important purpose in some areas is to ensure what is called interoperability. For example, there are standards which define screw threads, the prime purpose of which is to ensure that nuts fit bolts. In the information and communications technology arena, there are many standards concerned with interoperability, such as standards for encoding images JPEG, which allow pictures to be shared easily.

Second, there are standards that enshrine best practice and aim to ensure that products, systems, or services meeting these standards perform at some specified level. For example, there are standards for life jackets that aim to ensure that they provide an appropriate level of buoyancy that ensures that people who have to abandon vessels can be kept in a position that allows them to breathe (i.e., face up out of the water) even if they were unconscious. In the usability standards area, there are hardware standards which aim to ensure that computer displays meeting them provide an appropriate level of visibility that ensures that people who use them will be able to read them in typical office environments. There are software usability standards which aim to ensure that dialog screens are designed to match the users and the tasks they are performing and take account of relevant user psychology and cognitive processes.

35.2.1.1 Best Practice

International usability standards are primarily concerned with providing definitive statements of good practice. The growing field of usability and more recently user experience (UX) is filled with experts offering their own, often conflicting, views of good practice. There are those who argue that user interface design should be regarded as a science and that systematic user research and usability testing techniques are essential in order to design a usable interface. There are others, the most notable example being the late Steve Jobs who famously said in a magazine interview that "You can't just ask the customers what they want and then try to give that to them. By the time you get it built, they'll want something new."

The truth probably lies somewhere between these two extremes. Simply relying on user research will not result in the kind of highly innovative interfaces for which Apple has been famous. However, simply relying on creatively guessing user needs is not enough, and even Apple has conducted extensive testing of its ideas and prototypes with many not making it to market.

In this volatile arena, international usability standards can provide independent and authoritative guidance. International standards are developed slowly, by consensus, using extensive consultation and development processes. This has its disadvantages in such a fast-moving field as user interface design, and some have criticized any attempts at standardization as premature. However, there are areas where a great deal is known about good design practices which can be made accessible to designers through appropriate standards (Dzida et al. 1978; Shneiderman 1987; Sperandio 1987; Newman and Lamming 1995). There are approaches to user interface standardization, based on human characteristics, which are relatively independent of specific design solutions or technologies (e.g., display technology).

The practical discipline of having to achieve international consensus helps moderate some of the wilder claims of user interface enthusiasts and helps ensure that the resulting standards do indeed represent good practice. Although the slow development process means that usability standards can seldom represent the leading edge of design, nonetheless, when properly written, they need not inhibit creativity. Indeed, as discussed later, the development of process standards avoids the trap of limiting standards to current technology. Another approach—which not only does not inhibit creativity but actually enhances it—involves the development of user-based test methods (as exemplified in ISO 9241-304:2008). In this standard, the check for conformance involves comparing the performance of a user executing a standard task on a reference display (which meets the standard) and the new display. If the performance on the new display is as good as or better than the reference display, the new display passes. Since the task involves reading and recognizing characters on the display, it does not matter what technology is used. The test simply checks the performance of the user viewing the display. Similar tests have also been agreed for keyboards and other input devices. Far from limiting creativity, these test standards encourage designers to develop even more innovative technical solutions that work well for their users.

35.2.1.2 Common Understanding

Another problem in the field of usability and user experience is that there are many views not only about the potential interface solutions but also about the terminology involved at all stages. Even what the main players involved in designing systems for people should be called can become a point of argument—are they UX designers? Information designers or architects? Interaction or interface designers? What happened to system designers, developers, software designers, and so on. Apart from potentially overlapping or conflicting roles, good usability design involves a number of different perspectives and viewpoints. One of the benefits of international usability standards is to provide a framework for different parties to share a common understanding when specifying interface quality in design, procurement, and use. International usability standards allow:

- Users to set appropriate procurement requirements and to evaluate competing suppliers' offerings
- Suppliers to check their products during design and manufacturing and provide a basis for making claims about the quality of their products
- Regulators to assess quality and provide a basis for testing products against national and international requirements

35.2.1.3 Consistency

Anyone who uses computers knows only too well the problems of inconsistency between applications and often even within the same application. Inconsistency, even at the simplest level, can cause problems. On the World Wide Web, inconsistency is very common. Even something as straightforward as a hypertext link may be denoted by underlining on one site, by a mouseover on a second site, and by nothing at all on a third site.

Usability standards can help organizations develop their own internal user interface standards and style guides to address this problem. Such documents can provide a consistent reference across design teams or across time to help avoid time-consuming and error-inducing inconsistency in the user interface.

35.2.1.4 Raising the Profile of User Interface Issues

One of the most significant benefits of international usability standardization is that it places user interface issues squarely on the agenda. Standards are serious business, and whereas many organizations may choose to pay little regard to research findings, few organizations can afford to ignore standards. Indeed in Europe, and increasingly in other parts of the world, compliance with relevant standards is a mandatory requirement in major contracts (Earthy et al. 2001).

35.2.2 Use of Language

It is important to understand that although ISs are written in English, French, or Russian (the three official languages of ISO, the International Organization for Standardization), there are extensive drafting rules, which mean that certain terms have quite specific meanings. For example, in the English versions of the standards, the use of the word "shall" means that something is necessary in order to meet the requirements in the standard. Meeting all the "shalls" in the standard is necessary in order to be able to claim that something "conforms" to the standard.

In the field of usability, there are few circumstances where there is only one solution and therefore where a "shall" is required. One of the frustrations that information systems designers experience is that when they ask a usability expert for advice, the answer usually start with "it depends … ." The reason for this is not that usability people share with politicians an unwillingness to give straight answers but rather a recognition that the "correct answer" depends on the context. So, for example, an apparently simple question such as "what is the maximum number of items that can be presented as a menu?" does not have a simple answer. If the menu is a simple drop-down list which the user will scroll down using a mouse or arrow key, then according to ISO 9241-14:2000 Menu Dialogues, that number is generally 7 ± 2 corresponding to short-term memory. However, if the menu is an alphabetic listing of every song on an iPod which will be accessed by the user touching a list which allows scrolling to be sped up or slowed down, then the answer is as many songs as the user possesses.

In practice, therefore, usability standards generally provide "guidance" and use the word "should" (in English versions) to reflect that this is a "recommendation" rather than a "requirement."

35.2.3 Conformance

International standards are generally voluntary, that is, it is up to the user of the standard to decide whether to follow a standard or not. In practice, however, especially in procurement conformance with standards may be required in order to satisfy the procuring organization. Conformance means complying with the mandatory requirements set out in the specific standard, usually indicated by the word "shall" in the text and a description on how to assess compliance in an annex (a test method).

As discussed earlier, many international usability standards do not contain many requirements and instead provide guidance, that is, "shoulds," which depend on the context. However, it is still

possible to claim conformance to such standards. One way is simply to declare that "all relevant recommendations in standard x have been followed." It is then up to the party to whom such a claim is made to assess whatever evidence is provided and determine whether they agree that the recommendations have been followed. Many user experience consultancies offer such evaluation services to their clients—both to suppliers wishing to make such claims about their products and to user organizations wishing to have suppliers' offerings assessed.

In some cases, the usability standards contain what is known as conditional compliance clauses. These standards do contain a "shall," that is, a mandatory requirement. That requirement typically stipulates that users of the standard shall determine which clauses and recommendations apply to their product, system, or service, and then detail how they determined that they met that requirement. For example, clause 4.3 in ISO 9241-14:1997 Menu Dialogues states, "If a product is claimed to have met the applicable recommendations in this part of ISO 9241, the procedure used in establishing requirements for, developing, and/or evaluating the menus shall be specified. The level of specification of the procedure is a matter of negotiation between the involved parties. Users of this part of ISO 9241 can either utilize the procedures provided in Annex A, or develop another procedure tailored to their particular development and/or evaluation environment."

35.2.4 How ISO Develops International Standards

The ISO is the world's largest developer and publisher of ISs. Its members are the National Standards Bodies (NSBs) of 162 countries. It is supported by a Central Secretariat based in Geneva, Switzerland. The principal deliverable of ISO is the IS.

Standards development work is conducted by technical committees (TCs) and subcommittees (SCs) which meet every year or so and are attended by formal delegations from participating members of that committee. In practice, the technical work takes place in working groups (WGs) of experts, nominated by national standards committees but expected to act as independent experts. Most NSBs set up "mirror committees" to coordinate their input to the international work.

- The work starts when a new work item (NWI) is proposed identifying a suitable topic for standardization. This proposal document is circulated for vote to the appropriate TC or SC.
- If approved, it is passed to a WG to be developed into a working draft (WD), which is a partial or complete first draft of the text of the proposed standard. The work is usually done by a project editor with members of the WG.
- The first formal stage is to produce and circulate a committee draft (CD) and circulate it for comment and approval within the committee and the national mirror committees. It is not unusual for a second CD to be required if there is significant disagreement over the first CD.
- The first public stage is a draft international standard (DIS), which is circulated widely for public comment via the NSBs.
- Once this is approved and any relevant comments addressed, it is issued as final DIS. At this stage, no further substantive comments are permitted, except a final go/no go vote.
- Eventually (under ISO rules, each stage takes a minimum of 3–6 months to allow for full review in each country), a final IS is published.

35.3 Impact on Practice

ISO usability standards have become increasingly important in the design of information systems and technology. They are specified in many procurement contracts, and most major software developers rely on them to demonstrate the quality of their products. Their history stretches back over more than 30 years.

35.3.1 Early History of ISO Usability Standards

Usability standards have been under development by ISO since 1983 when a NWI with the title "Visual Information Processing" was approved. This work item became the responsibility of ISO TC159 SC4 Ergonomics of human–system interaction, and after several years work resulted in a 17-part standard ISO 9241 entitled "Ergonomic requirements for office work with visual display terminals." The focus on office work reflected concerns at the time about the impact of VDU use on people's health, but many of the parts of ISO 9241 dealt with broader usability and software interface issues. It has been an influential standard across the world and is referenced in many countries' regulations, including the United Kingdom's Health and Safety (display screen equipment) Regulations 1992 (Stewart 1992). Thirty five countries take part in the standards work and many go on to adopt the ISs as national standards.

When it came to revising this standard, the committee wanted both to retain the ISO 9241 "brand" which had become a recognized benchmark and also to broaden its scope. A new title "The Ergonomics of Human–System Interaction" reflected this ambition, and the multipart structure allowed the committee to integrate other usability standards.

The structure reflected the numbering of the original ISO 9241 standard; for example, displays were originally Part 3, and became the 300 series. In each section, the "hundred" is an introduction to the section, for example, Part 100 gives an introduction to the software ergonomics parts. The number of parts that will be developed in each section varies depending on the complexity of the area and the need for specific standards.

Only three part numbers have been retained (following revision) from the original ISO 9241 structure, as these address issues that apply across all other parts of ISO 9241:

Part 1 Introduction
Part 2 Job design
Part 11 Hardware and software usability

An additional part that also applies across all of ISO 9241 is

Part 20 Accessibility and human–system interaction

The remaining parts are structured in "hundreds" as follows:

100 series Software ergonomics
200 series Human–system interaction processes
300 series Displays and display-related hardware
400 series Physical input devices—ergonomics principles
500 series Workplace ergonomics
600 series Environment ergonomics
700 series Application domains—control rooms
900 series Tactile and haptic interactions

35.3.2 How Do You Apply Usability Standards in Practice?

During the development of ISO 9241, it became clear that user interface technology was developing so quickly that the traditional approach to standards could not keep up in all areas. Two solutions were adopted for this problem.

First, standards concerned with hardware including displays and input devices contained what were known as "user performance test methods" as well as conventional hardware test methods. These user performance test methods allowed a new device to be used under controlled conditions by a defined group of participants performing specific tasks. The performance of the participants was then compared with their performance on a test device, which met the standard. If the participants' performance was as good or better on the test device, then this device was deemed to pass. This approach means that any

technology can be tested if it is designed to allow users to perform suitable tasks, for example, read text on a screen, or enter characters into a system.

Second, it was realized that in many cases the best way to ensure that a design was usable was to follow a human-centered design process. Human-centered design is an approach to developing and acquiring software that improves system effectiveness and the efficiency and satisfaction of users (usability). Following this systematic framework helps reduce the risk that new software is unusable or fails to work properly for its intended users. Across all industries and governments, major software development projects are notorious for being delivered late and overbudget. Worse still, they often fail to deliver the service promised (Clegg et al. 1997). In hindsight, the problems are often due to a failure to engage fully with all stakeholders, especially those intended to operate and use the systems. Furthermore, excessive ambition which overlooks the reality of existing working practices, and design and development methods which are rigid, inflexible, and unable to adapt to emerging business needs and changes in the environment are also reasons for failure. In 1999, ISO TC159 SC4 published a new standard ISO 13407 on Human-Centered Design for Interactive Systems. The standard provides a systematic framework, which directly addresses these and other problems in delivering usable software, products, and services. It is aimed at Project Managers and describes how they can apply human-centered design processes to procure or develop technical software that will deliver value to the users and the business. This standard presents four principles of human-centered design, including the iteration of design solutions and the active involvement of users. It also describes key activities including the need to understand and specify the context of use, produce designs and prototypes of potential solutions, and evaluate these solutions against the human-centered criteria. The term human-centered design was used in preference to user-centered design, because the process includes all stakeholders, not just those usually considered as users.

Both approaches have been adopted widely, and the new parts of ISO 9241 that deal with displays and input devices both contain user performance test methods. Human-centered design has been recognized as the best way to develop usable systems, and the standard has been endorsed by such bodies as the Usability Professionals Association and the International Ergonomics Association.

The human-centered design approach is complementary to existing design methodologies—it does not describe all the processes that are necessary to design and develop a system. It is characterized by the following:

- Systems are designed to take account of all the people who will use them and other stakeholder groups, including those who might be affected (directly or indirectly) by their use. Constructing systems based on an inappropriate or incomplete understanding of user needs is one of the major sources of systems failure.
- Users are involved throughout design and development. This provides knowledge about the context of use, the tasks, and how users are likely to work with the future system. User involvement should be active, whether by participating in design, acting as a source of relevant data, or by evaluating solutions.
- The design is driven and refined by user-centered evaluation. Early and continuous feedback from users minimizes the risk that the system does not meet user and organizational needs (including those requirements that are hidden or difficult to specify explicitly). Such evaluation ensures preliminary design solutions are tested against "real world" scenarios, with the results being fed back into progressively refined solutions. User-centered evaluation should also take place as part of final acceptance of the product to confirm that requirements have been met. Feedback from users during operational use identifies long-term issues and provides input to future design.
- The process is iterative. For complex systems, it is impossible to specify completely and accurately every aspect of the interaction at the beginning of development. Initial design solutions rarely satisfy all the user needs. Many users and stakeholders need only emerge during development, as the designers refine their understanding of the users and their tasks, and as users provide feedback on potential solutions.

- The design addresses the whole user experience. This involves considering, where appropriate, organizational impacts, user documentation, on-line help, support and maintenance (including help desks and customer contact points), training, and long-term use.
- The design team reflects a range of skills and perspectives. The team does not have to be large, but should be sufficiently diverse to understand the constraints and realities of the various disciplines involved. This can have other benefits too. For example, technical experts can become more sensitized to user issues, and the users themselves can become more aware of technical constraints.

35.3.3 Using Standards to Support Human-Centered Design

Although, as explained earlier, the human-centered design standard ISO 13407 was developed in parallel with ISO 9241, many parts of ISO 9241 were developed with an implicit human-centered design process in mind. These parts can also be used to support specific design activities whether or not a full human-centered design process is being followed. Therefore, the next section describes the human-centered design process, originally specified in ISO 13407, and explains how the various parts of ISO 9241 can be used to support this process.

As part of the overall restructuring of ISO 9241 mentioned earlier, the opportunity was taken when ISO 13407 was undergoing its systematic review (a key part of the ISO process to ensure continued relevance) to incorporate it within the new ISO 9241 structure as ISO 9241-210:2010 Human-centered design for interactive systems. The revised standard remained largely unchanged, with one major exception. The four key human-centered design activities were no longer just recommendations; they became "requirements." This meant that people could now claim conformance, that is, that they followed and adhered to the ISO 9241-210 human-centered design process. To do so, they have to ensure that they

- Understand and specify the context of use (including users, tasks, environments)
- Specify the user requirements in sufficient detail to drive the design
- Produce design solutions which meet these requirements
- Conduct user-centered evaluations of these design solutions and modify the design taking account of the results

Note that the requirement is to provide evidence to show that they have done these successfully. There is no requirement to produce lots of documents to conform to the standard. The onus is on the organization claiming conformance to provide whatever level of detailed evidence the recipient requires.

In addition to these four activities, the standard provides guidance and recommendations on how to plan the human-centered design process and how to follow-up to ensure that the system is implemented properly. These six main steps are described in the following sections, and the other parts of ISO 9241, which support these steps, are explained and described briefly.

Standards development is an ongoing process, and standards can change radically during the various stages. The tables therefore only reference ISO standards that have been published up to February 2012.

35.3.3.1 Planning When and How the Human-Centered Design Activities Fit in the Program

The Project Manager should prepare the plan, which shows how the human-centered activities integrate into the overall project plan. Where the software is being developed in-house within the organization, the Project Manager creates the plan directly ensuring due time and resources are scheduled to allow the human-centered activities to be undertaken properly and any results fed back into the overall development process.

Where software is being purchased from an external supplier, there are two options:

1. The software is already available "off the shelf."
2. Significant customizing and development are required.

In option 1, the Project Manager only has to plan any organization-specific activities involved in selecting, evaluating, or implementing the software.

In option 2, the Project Manager requires the supplier to provide the plan, taking full account of the time and resources, which may be required from the organization, to participate in user research, requirements gathering, user testing, and any other user-based activities.

Underestimating the extent of user interaction required is a common feature of projects that do not plan human-centered design appropriately. For example, a system may be initially intended to be fully automated but ends up requiring significant user interaction, which then has to be designed in a rush without a sound understanding of the context of use.

The level of detail in the plan will vary depending on the scale of the project, the degree of user interaction expected, and the risks associated with poor usability or user rejection of the system.

The plan

- Identifies appropriate methods and resources for the human-centered activities
- Defines how these and their outputs fit with other system development activities
- Identifies the individuals and the organization(s) responsible for the human-centered design activities and the range of skills and viewpoints they provide
- Describes how user feedback and communication are collected and communicated
- Sets appropriate milestones and timescales for human-centered activities within the overall plan (allowing time for user feedback, and possible design changes, to be incorporated into the project schedule)

The plan for human-centered design is subject to the same project disciplines (e.g., responsibilities, change in control) as other key activities.

Time should also be allocated within the plan for communication among design team participants. Time spent resolving usability issues early in the project will deliver significant savings at later stages (when changes are, inevitably, more costly).

Human-centered design activities should start early in the project (e.g., at the initial concept stage) and continue throughout the life of the project (Table 35.1).

35.3.3.2 Understand and Specify the Context of Use (Including Users, Tasks, Environments)

The characteristics of the users, their tasks, and the organizational, technical and physical environment define the context in which the system is used (the context of use).

TABLE 35.1 Parts of ISO 9241 and Associated Standards Relevant to Planning

Relevant parts of ISO 9241	Brief Description
ISO 9241-210:2010 Human-centered design for interactive systems (supersedes ISO 13407 1999)	This part provides guidance on and requirements for the human-centered design process and is aimed at those responsible for managing the design of interactive systems.
ISO/TR 18529:2000 Human-centered life cycle process descriptions	Uses the ISO standard format for process models to describe the processes necessary for ensuring human-centered design content in systems strategy.

TABLE 35.2 Parts of ISO 9241 Relevant to Understanding and Specifying the Context of Use

Relevant Part of ISO 9241	Brief Description
ISO 9241-11:1998 Guidance on usability	Defines usability as "Extent to which a product can be used by specified users to achieve specified goals with effectiveness, efficiency, and satisfaction in a specified context of use," and provides guidance on how to address usability in design projects.

The context of use description includes details of the following:

- The users and other stakeholder groups.
- The user profile in terms of relevant knowledge, skill, experience, training, physical attributes (e.g., any disabilities), preferences, and capabilities of the users.
- The environment profile in which the system will operate the technical environment, including the hardware, software, and materials; the relevant characteristics of the physical environment, including thermal conditions, lighting, spatial layout, and furniture.
- The user task profile, including the frequency and duration of tasks and interdependencies (Table 35.2).

The user, environment, and task profiles should be described in sufficient detail to support the requirements, design, and evaluation activities. They are working documents that start as outlines, and are reviewed, maintained, extended, and updated during the design and development process.

The next step is to turn the profiles into concrete, detailed usage "scenarios" and "personnas" (Dzida 1998). Scenarios are realistic stories that describe the use of the software from the user's perspective and are combinations of individual tasks in the right sequence to achieve an overall goal. Personnas are rich descriptions of target users.

The scenarios and personnas provide a high-level summary of the key goals, which the software is intended to support, in user-centered language.

Where the software is being custom-developed (whether in-house or by an external supplier), the scenarios and personnas help communicate how the users will expect to use the software and what they will want to achieve from it. Designers find these kinds of descriptions useful in maintaining a focus on the user when designing specific functionality.

Where software is being purchased "off the shelf" from an external supplier, the scenarios help the software selectors understand the user's context and communicate this to potential suppliers.

In both situations, the scenarios provide a consistent framework for the subsequent evaluation of emerging or proposed designs.

35.3.3.3 Specify the User Requirements in Sufficient Detail to Drive the Design

Identifying user needs and specifying the functional and other requirements for the system are major software development activities. When following the human-centered design approach, these activities are extended to create an explicit specification of user requirements in relation to the context of use and the objectives of the system (Table 35.3).

The user requirements specification should be

- Stated in terms that permit subsequent testing
- Verified by the relevant stakeholders
- Internally consistent
- Updated as necessary, during the life of the project

This specification is then used to drive the design and provide agreed quality measures used to evaluate the software.

TABLE 35.3 Parts of ISO 9241 Relevant to Specifying the User Requirements

Relevant Parts of ISO 9241	Brief Description
ISO 9241-11:1998 Guidance on usability	Defines usability as "Extent to which a product can be used by specified users to achieve specified goals with effectiveness, efficiency, and satisfaction in a specified context of use," and provides guidance on how to address usability in design projects.
ISO 9241-20:2009 Accessibility guidelines for information/communication technology equipment and services	A high-level overview standard covering both hardware and software. It covers the design and selection of equipment and services for people with a wide range of sensory, physical, and cognitive abilities, including those who are temporarily disabled, and the elderly.

These quality measures should

- Capture the key success factors for the product and what value it will deliver for users.
- Summarize who will be doing what and under what circumstances.
- Identify the type of measures to be used (e.g., performance data, user preference data, or conformance to standards).
- Specify the level that the software must achieve to be released to users. Scores below that level mean that the products must be improved. Scores above that level may mean that resources have been wasted.

35.3.3.4 Produce Design Solutions That Meet These Requirements

There are several chapters in this handbook that provide guidance for the design of usable software. Within the ISO 9241 series of standards, there are several standards that provide detailed guidance, but the overall process involves six main steps in designing usable software.

1. Structure solutions around key tasks and workflows based on the context of use and user requirements specification. A key issue concerns establishing an appropriate "allocation of function"—deciding which system tasks are to be automated and which should be under user control. Table 35.4 lists standards relevant to designing jobs and tasks.
2. Design the interaction, interface, and navigation from the user's perspective and keep them consistent. Be aware of other software that the user is likely to be using, and be cautious about introducing different styles of interface. Table 35.5 lists standards relevant to designing dialogs and navigation.
3. Define the navigation and keep it consistent. If different teams are developing separate parts of the software, maintain consistency by establishing an agreed style guide at the beginning of the development.
4. Follow interface design best practice. Various parts of ISO 9241 offer guidance and are based on internationally agreed best practice for achieving usable hardware and software (see Tables 35.6 through 35.8). The HCI Bibliography website lists more than 53 journals, many peer-reviewed, relevant to usability and human–computer interaction (HCI Bibliography 2012).

TABLE 35.4 Parts of ISO 9241 Relevant to Designing Jobs and Tasks

Relevant Part of ISO 9241	Brief Description
ISO 9241-2:1992 Guidance on task requirements deals with the design of tasks and jobs involving work with visual display terminals	Provides guidance on how task requirements may be identified and specified within individual organizations and how task requirements can be incorporated into the system design and implementation process.

TABLE 35.5 Parts of ISO 9241 Relevant to Designing User–System Dialogs and Interface Navigation

Relevant Parts of ISO 9241	Brief Description
ISO/TR 9241-100:2010 Introduction to standards related to software ergonomics	Provides an introduction to the "100 series" of ISO 9241 software parts. Published as a TR, which has a shorter development time than a full IS. This will allow it to be updated regularly to reflect the current content and structure of ISO 9241.
ISO 9241-110:2006 Dialog principles (supersedes ISO 9241 10:1996)	Sets out seven dialog principles and gives examples. The dialog should be suitable for the task (including the user's task and skill level); self-descriptive (it should be obvious what to do next); controllable (especially in pace and sequence); conform to user expectations (i.e., consistent); error-tolerant and forgiving; suitable for individualization and customizable; and should support learning.
ISO 9241-129:2010 Guidance on software individualization	This part provides ergonomics guidance on individualization within interactive systems, including recommendations on where individualization might be appropriate or inappropriate and how to apply individualization. The standard provides general guidance on individualization rather than specific implementations of individualization mechanisms. It is intended to be used along with other parts of ISO 9241—not in isolation.
ISO 9241-14:2000 Menu dialogues	Recommends best practice for designing menus (pop-up, pull-down, and text-based menus). Topics include menu structure, navigation, option selection, and menu presentation (including placement and use of icons). One of the annexes contains a 10-page checklist for determining compliance with the standard.
ISO 9241-15:1998 Command dialogues	This part provides recommendations for the ergonomic design of command languages used in user–computer dialogs. The recommendations cover command language structure and syntax, command representations, input and output considerations, and feedback and help. Part 15 is intended to be used by both designers and evaluators of command dialogs, but the focus is primarily toward the designer.
ISO 9241-16:1999 Direct manipulation dialogues	This part provides recommendations for the ergonomic design of direct manipulation dialogs, and includes the manipulation of objects, and the design of metaphors, objects, and attributes. It covers those aspects of "Graphical User Interfaces," which are directly manipulated, and not covered by other parts of ISO 9241. Part 16 is intended to be used by both designers and evaluators of command dialogs, but the focus is primarily toward the designer.
ISO 9241-143:2012 Forms	ISO 9241-143:2012 provides requirements and recommendations for the design and evaluation of forms, in which the user fills in, selects entries for, or modifies labeled fields on a "form" or dialog box presented by the system. It contains guidance on the selection and design of interface elements relevant to forms. The requirements and recommendations can be used during design, as a basis for heuristic evaluation, as guidance for usability testing, and in the procurement process. It replaces ISO 9241-17:1998 Form-filling dialogs
ISO 9241-151:2008 Guidance on World Wide Web user interfaces	Sets out detailed design principles for designing usable websites—these cover high-level design decisions and design strategy; content design; navigation; and content presentation.
ISO9241-171:2008 Guidance on software accessibility	Aimed at software designers and provides guidance on the design of software to achieve as high a level of accessibility as possible. Replaces the earlier Technical Specification ISO TS 16071:2003 and follows the same definition of accessibility—"usability of a product, service, environment, or facility by people with the widest range of capabilities." Applies to all software, not just web interfaces.

TABLE 35.6 Parts of ISO 9241 Relevant to Designing or Selecting Displays

Relevant Parts of ISO 9241	Brief Description
ISO 9241-300:2008 Introduction to electronic visual display requirements (The ISO 9241-300 series supersedes ISO 9241, parts 3, 7, and 8)	A very short (four pages) introduction to the ISO 9241-300 series, which explains what the other parts contain.
ISO 9241-302:2008 Terminology for electronic visual displays	Definitions, terms, and equations that are used throughout ISO 9241:300 series.
ISO 9241-303:2011 Requirements for electronic visual displays	Sets general image quality requirements for electronic visual displays. The requirements are intended to apply to any kind of display technology.
ISO 9241-304:2008 User performance test methods for electronic visual displays	Unlike the other parts in the subseries which focus on optical and electronic measurements, this part sets out methods which involve testing how people perform when using the display. The method can be used with any display technology.
ISO 9241-305:2008 Optical laboratory test methods for electronic visual displays	Defines optical test methods and expert observation techniques for evaluating a visual display against the requirements in ISO 9241-303. Very detailed instructions on taking display measurements.
ISO 9241-306:2008 Field assessment methods for electronic visual displays	Provides guidance on how to evaluate visual displays in real-life workplaces.
ISO 9241-307:2008 Analysis and compliance test methods for electronic visual displays	Supports ISO 9241-305 with very detailed instructions on assessing whether a display meets the ergonomics requirements set out in part 303.
ISO/TR 9241-308:2008 Surface-conduction electron-emitter displays	Technical report on a new "ecofriendly" display technology called "Surface-Conduction Electron-Emitter Displays."
ISO/TR 9241-309:2008 Organic light-emitting diode displays	Technical report on another new display technology called "organic light emitting diode displays," which are better for fast-moving images than LCDs.
ISO/TR 9241-310:2010 Visibility, aesthetics, and ergonomics of pixel defects	Pixel defects are controversial. Users expect none, but would not be willing to pay the extremely high price that would be charged to achieve this. This TR explains the current situation and gives guidance on the specification of pixel defects, visibility thresholds, and aesthetic requirements for pixel defects.
ISO 9241-12:1999 Presentation of information	This part contains specific recommendations for presenting and representing information on visual displays. It includes guidance on ways of representing complex information using alphanumeric and graphical/symbolic codes, screen layout, and design as well as the use of windows.

5. Produce sketches and mock-ups early to test assumptions. Using scenarios and simple sketches or mock-ups enables the designers to communicate the proposed design to users and other stakeholders to obtain feedback before design decisions are finalized.
6. Keep testing emerging solutions with users until the quality criteria are met. Human-centered evaluation can take place throughout the design process from initial concepts to final (signed-off) designs.

One example of the kind of high-level guidelines in ISO 9241 is reproduced in simplified form in Table 35.9, which is based on ISO 9241-110:2006 Dialogue Principles.

See Table 35.10 for standards relevant to selecting usability methods for design and evaluation.

TABLE 35.7 Parts of ISO 9241 Relevant to Designing or Selecting Keyboards and Other Input Devices

Relevant Parts of ISO 9241	Brief Description
ISO 9241-4:1998 Keyboard requirements (some clauses in this standard have been superseded by ISO 9241-400 and ISO 9241-410	This part specifies the ergonomics design characteristics of an alphanumeric keyboard, which may be used comfortably, safely, and efficiently to perform office tasks.
ISO 9241-400:2007 Principles and requirements for physical input devices	Sets out the general ergonomics principles and requirements, which should be taken into account when designing or selecting physical input devices.
ISO 9241-410:2008 Design criteria for physical input devices (supersedes ISO 9241-9: 1998)	Describes ergonomics characteristics for input devices, including keyboards, mice, pucks, joysticks, trackballs, touchpads, tablets, styli, and touch-sensitive screens. The standard is aimed at those who design such devices and is very detailed.
ISO 9241-420:2011 Selection of physical input device	Provides ergonomics guidance for selecting input devices for interactive systems. It describes methods for evaluating a wide range of devices from keyboards and mice to pucks, joysticks, trackballs, trackpads, tablets and overlays, touch-sensitive screens, styli, and light pens. It encourages user organizations and systems integrators to consider the limitations and capabilities of users and the specific tasks and context of use when selecting input devices.
ISO 9241-910:2011 Framework for tactile and haptic interaction	Provides a framework for understanding and communicating various aspects of tactile/haptic interaction. It defines terms, describes structures and models, and also serves as an introduction to the other parts of the ISO 9241 "900" subseries. It provides guidance on how tactile/haptic interaction can be applied to a variety of user tasks. It does not specifically cover gesture-based interfaces, although it does offer some relevant guidance for understanding such interactions.
ISO 9241-920:2009 Guidance on tactile and haptic interactions	Gives recommendations for tactile and haptic hardware and software interactions. It provides guidance on the design and evaluation of hardware, software, and combinations of hardware and software interactions. It does not provide recommendations specific to Braille, but can apply to interactions that make use of Braille.

TABLE 35.8 Parts of ISO 9241 Relevant to Designing or Workplaces for Display Screen Users

Relevant Parts of ISO 9241	Brief Description
ISO 9241-5:1999 Workstation layout and postural requirements	This part specifies the ergonomics requirements for a visual display terminal workplace, which will allow the user to adopt a comfortable and efficient posture.
ISO 9241-6:2000 Guidance on the work environment	This part specifies the ergonomics requirements for the visual display terminal working environment, which will provide the user with comfortable, safe, and productive working conditions.

TABLE 35.9 Usability Principles (Based on ISO 9241-110)

1. Fit with user's task

The interface should match the way users perform their tasks

1.1 Are screens designed to provide users with the relevant information they need to complete tasks?

1.2 Is only necessary information displayed?

1.3 Does the system accept input and produce output in useful and appropriate formats?

1.4 Do input fields contain useful default values?

1.5 Is the sequence of actions required optimum? (i.e., all that is needed, but no more)

1.6 If paper documents are needed for the task, do the screens match their format?

2. Sign posting

The users should be able to tell from the screens, where they are in the task and what they can do next

2.1 Do the screens guide the user what to do next?

2.2 Can most users work without needing to refer to manuals?

2.3 Is it obvious when input is required or about to be required?

2.4 Is it clear what input is required?

2.5 Is it clear how to interact with the different system components?

2.6 Do input fields indicate what format and units are required (for example, dd/mm/yyyy)?

3. Intuitiveness

The system should respond to the task context and follow accepted conventions for the target users

3.1 Is the terminology appropriate to the target users?

3.2 Is there timely feedback on users' actions?

3.3 Are users given useful feedback on response times?

3.4 Do the data structures correspond to users' expectations?

3.5 Is there sufficient and useful feedback to users?

3.6 Are the behavior and appearance of the system consistent throughout?

3.7 Does the input focus default appropriately?

3.8 Are system messages useful and constructive?

3.9 Is the interface suitable for users who do not have English as their first language?

4. Learnability

The system should support learning

4.1 Does the system provide explanations which help users learn?

4.2 Are there prompts and reminders to help users learn?

4.3 Is sufficient support available to help infrequent users?

4.4 Does the system help users build a mental model of what is going on?

4.5 Can users see the steps needed to complete a task?

4.6 Does the system minimize the amount of input required (e.g., using autocomplete)?

4.7 Does the system encourage users to explore (if appropriate) without negative consequences?

5. User control

The user should be able to control the interaction

5.1 Can the user control the pace of the interaction?

5.2 Can the user control the sequence of steps?

5.3 Does the system allow the user to restart their task if necessary?

5.4 Does the system offer an "undo" where possible?

5.5 Can the user control the amount of data displayed at a time?

5.6 Does the system support alternative input/output devices?

5.7 Can users set appropriate default values?

5.8 If appropriate, can users "track changes" and view original data after a modification?

(*continued*)

TABLE 35.9 (continued) Usability Principles (Based on ISO 9241-110)

6. Error tolerance
The system should minimize the likelihood and severity of errors
6.1 Does the system help minimize input errors?
6.2 Is the system robust?
6.3 Are error messages helpful for correcting the error?
6.4 Does the system actively support error recovery?
6.5 If automatic error correction is provided, can users override this functionality?
6.6 Can users continue (where appropriate) and defer correcting an error until a more suitable time?
6.7 Can users get additional help for errors?
6.8 Does the system validate input data before processing?
6.9 Has the number of steps for error correction been minimized?
6.10 Does the system require confirmation for potentially critical actions?
7. Customizing
Users should be able to customize the system to suit their skills and preferences
7.1 Can the system be tailored to suit different user profiles?
7.2 Can the user customize how data is displayed?
7.3 Can the help information be tailored for users with different skills?
7.4 Can users customize system speed and sensitivity?
7.5 Can users choose different interaction styles, for example, command line versus GUI?
7.6 Can users choose from a variety of interaction methods (e.g., keyboard vs. mouse)?
7.7 Can users customize how input/output data is displayed, to a degree that meets their needs?
7.8 Can users customize the interface or functionality to suit their task requirements and preferences?
7.9 Can users modify names of objects and actions to suit their requirements?
7.10 Can default settings be restored?

TABLE 35.10 Standards Relevant to Selecting Usability Methods for Design and Evaluation

Relevant Standard	Brief Description
ISO/TR 16982:2002 Usability methods supporting human-centered design	Provides information on human-centered usability methods, which can be used for design and evaluation. It details the advantages, disadvantages, and other factors relevant to using each usability method.

35.3.3.5 Conduct User-Centered Evaluations of These Design Solutions and Modify the Design, Taking Account of the Results

User-centered evaluation (evaluation based on the users' perspective) is at the heart of human-centered design. It occurs throughout the design life cycle from initial testing of concepts to final testing to confirm that the software meets the quality criteria.

There are two main approaches:

- Inspection-based evaluation
- User-based testing

35.3.3.5.1 Inspection-Based Evaluation

Inspection-based evaluation helps eliminate major issues before user testing (and hence makes the user testing more cost-effective). It is ideally performed by usability experts, with broad experience of problems encountered by users, working with domain experts who understand the software and the problem

domain. Inspection can be based on task scenarios or on guidelines and standards, for example, the Web Content Accessibility Guidelines (WCAG).

During the development process, or where there are no users already familiar with the software, inspection-using scenarios can be used. This involves the assessor putting themselves in the position of the user working through the scenarios agreed in the requirements stage. This can be done with working prototypes or with partial prototypes or even nonfunctioning mock-ups of the software. At the very early stages in design, these mock-ups can be simple sketches on paper, or at a slightly later stage, PowerPoint screenshots with hotspots to simulate functionality. The assessor works through the tasks in the scenario and notes any issues, for example, points in the sequence where it is not clear what to do next or where the result is unexpected. The objective is to identify breaks in flow and incomplete or unclear screens and dialogs at an early enough stage for them to be changed quickly and cheaply. Delaying assessing early designs is not only wasteful, but also tends to inhibit assessors who may be reluctant to recommend changes, which they think may be time-consuming or expensive. Starting assessment early also provides a useful benchmark, which shows how the design has improved, as it is modified, based on user-centered feedback.

Inspection-based evaluation can also be conducted using guidelines and standards. Software accessibility, the degree to which software can be used by people with disabilities, is one area where it can be necessary to check compliance with published external standards. In particular, the WCAG, published by the World Wide Web Consortium (W3C), are the widely accepted accessibility standards for web-based applications. More information on available standards to support inspection is shown in Tables 35.5 through 35.10.

35.3.3.5.2 User Testing

User testing can be undertaken at any stage of the design and development cycle. At an early stage, users can be presented with sketches or mock-ups of design concepts and asked to evaluate them by working through how they would carry out key tasks. This provides much more information than simply showing or demonstrating them to users. For instance, scenarios could be used to provide a useful framework for structuring this walkthrough of the software. Later in development, user testing is used to confirm that the software meets the agreed quality criteria established earlier.

User testing is best conducted in a usability laboratory, which allows user behavior including detailed mouse and keyboard use to be observed and recorded for subsequent analysis. This can be supplemented with eye-tracking technology, which shows exactly where on the screen the users have been looking during the tasks. It can also be conducted more simply at the user's normal workstation by observing and video recording their behavior as they work through the tasks.

In addition to direct observations or measurements of user behavior (e.g., task completion times), user testing can involve users vocalizing their thought process while they perform the tasks. Further feedback can be obtained through questionnaires or interviews and checklists (before, during, or after the tasks).

The procedure for conducting user-based testing involves the following:

- Writing a test plan, which uses the scenarios to test the software against the release criteria, collects the relevant user behavior information, and identifies appropriate test participant profiles, for example, experienced user of competing product
- Ensuring that all stakeholders review and agree the plan in advance
- Recruiting the participants to the agreed profile
- Preparing the software, computer hardware, usability lab or other equipment, and questionnaires and checklists
- Conducting a pilot study to ensure that the testing is likely to produce the appropriate data for establishing whether the release criteria 3 have been met

- Conducting the formal test with the requisite number of participants (typically a minimum of three to four per unique user group) ensuring that the test conditions are randomized or balanced to avoid confounding learning effects or bias
- Analyzing and reporting the results in an agreed format with usability issues prioritized in terms of severity (see following paragraphs)
- Working with the design team to review the usability defects and decide on the basis of their severity, number of users affected, cost to fix, and how and when to fix them

The severity of usability defect is often classified as follows:

- Critical—the user is unable to use the software
- High—the user is severely restricted in using the software
- Medium—the user can circumvent the problem and use the software with only moderate inconvenience
- Low—the user can use the software with limitations, but these do not restrict its use

The Project Manager should ensure that the test plan is designed to allow the agreed quality criteria to be tested. Testers should be competent in conducting usability tests and follow the Usability Professionals Association or equivalent code of conduct. Where the user testing is being conducted by a third party, for example, independent usability specialists or usability teams within the software supplier, then the Project Manager may require the test reporting to follow ISO/IEC 25062:2006 software engineering—software products quality and requirements evaluation (SQuaRE)—common industry format (CIF) for usability tests.

When the testing is conducted internally, the worksheet presented in Table 35.11 (which is based on the full standard) may be used for reporting usability test results.

35.3.3.6 Implement the System with Appropriate Training and Support

The final stage in deploying a new software, whether it is developed in-house or purchased "off the shelf," is implementation.

Implementation involves a large number of technical processes to ensure that the new software (and/or hardware) operates properly in its environment. This includes tasks such as installation, configuration, testing, and making necessary changes before the software is finally deployed.

Human-centered design is complementary to and does not replace existing standards or processes for implementing the software.

Following a human-centered design process means that users are already prepared for the new software through their earlier involvement in requirements gathering and user testing. The scenarios identified earlier provide a useful basis for structuring any training required and also for other training and support materials, such as on-screen help and user manuals. Any usability issues that could not be fixed on time can be addressed through work-arounds and specific "frequently asked questions" (FAQs). While users find it convenient to ask more knowledgeable colleagues or dedicated support staff for help, one of the benefits of following a human-centered design process is that users require less support, even at implementation. This reduces the burden on colleagues and the dependence on costly on-site support.

Once the software is fully deployed, the final human-centered design activity is to track real world usage, not only to ensure that the original objectives were achieved but also to provide input to further development. Help desk data, log files, defect reports, user satisfaction surveys, and requests for changes, all provide valuable data. Formal follow-up evaluation can be carried out within a specific period, for example, 6 months to 1 year after system installation to test system performance and collect data on whether the user requirements were met.

Table 35.12 identifies standards relevant to reporting usability test results.

TABLE 35.11 Worksheet for Reporting Usability Test Results

Report title page
Name of the product and version that was tested
When the test was conducted?
Date the report was prepared
Contact name(s) for questions and/or clarifications
Background
Product name, purpose, and version
What parts of the product were evaluated?
The user population for which the product is intended
Test objectives
Description of context of use (note any difference between test context and real context)
Methods
Experimental design
Participant characteristics
Tasks and scenarios used
Test facilities
Computer configuration, including model, OS version, required libraries, or settings
Display devices, including screen size, resolution
Input devices, including make and model
Measures
Checklists, scoring sheets or questionnaires used—attach copies in the Appendix
Procedure including time limits on tasks and whether participants "thought aloud"
Participant instructions including task instructions—attach in Appendix
Metrics for effectiveness, completion rates, errors, and assists
Metrics for efficiency, completions rates/time on task
Metrics for satisfaction
Data analysis including any statistical analysis
Performance results
Satisfaction results
Appendices
Checklists, scoring sheets, and questionnaires used
Participant task instructions

Based on ISO/IEC 25062:2006 Software engineering: SQuaRE—Common Industry Format (CIF) for usability tests.

Check that the user test report contains at least the listed information to a sufficient level of detail to allow the validity and reliability of the findings to be assessed (✓ to confirm).

TABLE 35.12 Standards Relevant to Reporting Usability Test Results

Relevant Standard	Brief Description
ISO/IEC 25062:2006 Software product Quality Requirements and Evaluation (SQuaRE)—Common Industry Format (CIF) for usability test reports	Provides a standard method for reporting usability test findings. The format is designed for reporting results of formal usability tests in which quantitative measurements were collected, and is particularly appropriate for summative/comparative testing.

35.4 Research Issues

The relationship between international usability standards and research confuses some people. There are two major issues. First, although standards should be based on research evidence, research results themselves are not usually sufficient to determine what the standard should recommend or require. So, for example, in the standards concerned with identifying a suitable level of office illumination for work with visual display screens, research can show how individual sensitivity and acuity are affected by overall illumination level, image contrast, and so on. What such data show is that people vary in their sensitivity, and while some may be able to tolerate high ambient illumination, others will complain that their visual performance is significantly impaired. What the data itself cannot determine is where to set limits in the standard. The decision on where to set such limits involves a judgment on the part of the standards maker. Perhaps, this is more obvious in the area of workplace design. Human dimensions vary enormously, and so it is not realistic to design a single item of equipment to take account of the full range of human variability. In practice, many standards aim to address the middle 90% of the population and accept that the lower 5th percentile and the higher 95th percentile may not be accommodated. Such practicalities may be difficult for purist researchers to accept.

Second, much usability practice is closer to a craft than to a science. Usability practitioners regularly test systems with very small samples of participants, often as few as five. Anyone skilled in psychophysics knows that such small numbers make it almost impossible to draw reliable conclusions about the user population. However, even such small-scale testing can reveal useful and valuable data about some of the problems that real users may experience with the final product. And, there is a substantial body of practical data that can be used to guide user interface designers to improve the usability of their systems. But, the uncertainties associated with this body of practical experience mean that usability standards, especially international usability standards, can seldom be as prescriptive as traditional industry standards. Subtle differences in context can completely change the user experience, and emerging technology develops faster than the standards.

Both of these issues pose major problems for researchers wishing to support international usability standards. However, there is a need both for sound human-centered design and evaluation methods and for empirical data on new and emerging technologies. Therefore, data from well-constructed research studies will always be welcomed by the relevant standards committees.

In terms of future developments in usability standards, the path is not entirely clear. Some of the standards discussed here are based on human characteristics, and these are unlikely to change much. Although ISO standards go through a formal review process every 5 years, there seems little point in making major updates to standards which deal with human basics, such as visual perception. However, even if the principles are the same, there is evidence that readers and users of such standards are unlikely to trust them if the examples are out of date. There is, therefore, a need to continue to "refresh" such standards to ensure that they not only remain relevant but also appear to be most up-to-date.

In terms of future standardization efforts, new technological developments are likely to continue to generate new requirements. As discussed earlier, some usability standards are better written as process standards rather than product standards. However, experience shows that designers much prefer specific product standards, provided that they remain relevant. So, for example, work is currently underway in ISO TC159 SC4 WG2 to develop a technical report (TR) dealing with autostereoscopic displays, which can appear three-dimensional without the need for the viewer to wear glasses. Specific technical guidance in this chapter will help display designers avoid the many pitfalls in this emerging technology.

Ever more innovative interfaces are likely to emerge, requiring standard makers to remain agile and innovative in their efforts to ensure that all users can benefit from such developments in technology.

35.5 Summary

This chapter introduced the reader to international usability standards from the Human–System Interaction Committee of the ISO. It explained how standards are developed and the implications for how they can be used. It then went on to describe the human-centered design process as contained in ISO 9241, part 210 and explained how different standards can be used to support these human-centered design activities.

Further Information

Any readers who wish to get involved in the international usability standardization processes described in this chapter should contact their national standards body, which belongs to ISO and ask if it participates in ISO TC159 SC4. If it does, it will usually be able to put the reader in touch with a National Mirror Committee. If it does not, then it may be willing to become involved if there is sufficient support in that country.

36.1 Introduction

Usability is considered to be one of the most important quality factors for Web applications, along with others such as reliability and security (Offutt 2002). It is not sufficient to satisfy the functional requirements of a Web application in order to ensure its success. The ease or difficulty experienced by users of these applications is largely responsible for determining their success or failure. Usability evaluations and technologies that support the usability design process have therefore become critical in ensuring the success of Web applications.

Today's Web applications deliver a complex amount of functionality to a large number of diverse groups of users. The nature of Web development forces designers to focus primarily on time-to-market issues in order to achieve the required short cycle times. In this context, model-driven engineering (MDE) approaches seem to be very promising, since Web development can be viewed as a process of transforming a model into another model until it can be executed in a development environment. MDE has been successfully used to develop Web-based interactive applications. Existing approaches usually comprise high-level models (e.g., a presentation model, task model) that represent interactive tasks that are performed by the users of the Web application in a way that is independent from platforms and interaction modalities. From these models, the final Web application can be generated by applying model transformations.

Model-driven engineering approaches can play a key role in helping Web designers to produce highly usable Web applications. The intermediate models that comprise the Web application can be inspected

and corrected early in the development process, ensuring that a product with the required level of usability is generated. Although a number of model-driven Web development processes have emerged, there is a need for usability evaluation methods that can be properly integrated into these types of processes (Fernández et al. 2011). This chapter addresses this issue by showing how usability evaluations are integrated into a specific model-driven development method to ensure the usability of the Web applications developed.

36.2 Underlying Principles

Traditional Web development approaches do not take full advantage of the usability evaluation of interactive systems based on the design artifacts that are produced during the early stages of the development. These intermediate software artifacts (e.g., models and sketches) are usually used to guide Web developers in the design but not to perform usability evaluations. In addition, since the traceability between these artifacts and the final Web application is not well-defined, performing usability evaluations by considering these artifacts as inputs may not ensure the usability of the final Web application.

This problem may be alleviated by using a MDE approach due to its intrinsic traceability mechanisms that are established by the transformation processes. The most well-known approach to MDE is the model-driven architecture (MDA) defined by the object management group—OMG (2003). In MDA, platform-independent models (PIMs) such as task models or navigation models may be transformed into platform-specific models (PSMs) that contain specific implementation details from the underlying technology platform. These PSMs may then be used to generate the source code for the Web application (Code Model—CM), thus preserving the traceability among PIMs, PSMs, and source code.

A model-driven development approach therefore provides a suitable context for performing early usability evaluations. Platform-independent (or platform-specific) models can be inspected during the early stages of Web development in order to identify and correct some of the usability problems prior to the generation of the source code. We are aware that not all usability problems can be detected based on the evaluation of models since they are limited by their own expressiveness and, most importantly, they may not predict the user behavior or preferences. However, studies such as that of Hwang and Salvendy (2010) claim that usability inspections, applying well-known usability principles on software artifacts, may be capable of finding around 80% of usability problems. In addition, as suggested by previous studies (Andre et al. 2003), the use of inspection methods for detecting usability problems in product design (PIMs or PSMs in this context) can be complemented with other evaluation methods performed with end users before releasing a Web application to the public.

36.3 State of the Art in Usability Evaluation for Web Applications

Usability evaluation methods can be mainly classified into two groups: empirical methods and inspection methods. Empirical methods are based on observing, capturing, and analyzing usage data from real end users, while inspection methods are performed by expert evaluators or designers, and are based on reviewing the usability aspects of Web artifacts (e.g., mock-ups, conceptual models, user interfaces [UIs]), which are commonly UIs, with regard to their conformance with a set of guidelines.

The employment of usability evaluation methods to evaluate Web artifacts was investigated through a systematic mapping study in a previous work (Fernandez et al. 2011). This study revealed various findings:

1. There is lack of usability evaluation methods that can be properly integrated into the early stages of Web development processes.
2. There is a shortage of usability evaluation methods that has been empirically validated.

Usability inspection methods have emerged as an alternative to empirical methods as a means to identify usability problems since they do not require end user participation and they can be employed

during the early stages of the Web development process (Cockton et al. 2003). There are several proposals based on inspection methods to deal with Web usability issues, such as the cognitive walkthrough for the Web—CWW (Blackmon 2002) and the web design perspectives—WDP (Conte et al. 2007). Cognitive walkthrough for the Web assesses the ease with which a user can explore a website by using semantic algorithms. This method extends and adapts the heuristics proposed by Nielsen and Molich (1990) with the aim of drawing closer to the dimensions that characterize a Web application: content, structure, navigation, and presentation. However, these kinds of methods tend to present a considerable degree of subjectivity in usability evaluations. In addition, this method only supports ease of navigation.

Other works present Web usability inspection methods that are based on applying metrics in order to minimize the subjectivity of the evaluation, such as the WebTango methodology (Ivory and Hearst 2002) and the Web quality evaluation method—WebQEM (Olsina and Rossi 2002). The WebTango methodology allows us to obtain quantitative measures, which are based on empirically validated metrics for UIs, to build predictive models in order to evaluate other UIs. Web quality evaluation method performs a quantitative evaluation of the usability characteristics proposed in the ISO 9126-1 (2001) standard, and these quantitative measures are aggregated in order to provide usability indicators.

The aforementioned inspection methods are oriented toward application in the traditional Web development context; they are therefore principally employed in the later stages of Web development processes. As mentioned earlier, model-driven Web development offers a suitable context for early usability evaluations since it allows models, which are applied in all the stages, to be evaluated. This research line has emerged recently, and only a few works address Web usability issues, such as those of Atterer and Schmidt (2005), Abrahão and Insfran (2006), and Molina and Toval (2009).

Atterer and Schmidt (2005) proposed a model-based usability validator prototype with which to analyze models that represent enriched Web UIs. This approach takes advantage of models that represent the navigation (how the website is traversed) and the UI of a Web application (abstract properties of the page layout).

Abrahão and Insfran (2006) proposed a usability model to evaluate software products that are obtained as a result of model-driven development processes. Although this model is based on the usability subcharacteristics proposed in the ISO 9126 standard, it is not specific to Web applications and does not provide specific metrics. The same model was used by Panach et al. (2008) with the aim of providing metrics for a set of attributes that would be applicable to the conceptual models that are obtained as a result of a specific model-driven Web development process. Molina and Toval (2009) presented an approach to extend the expressivity of models that represent the navigation of Web applications in order to incorporate usability requirements. It improves the application of metrics and indicators to these models.

Nevertheless, to the best of our knowledge, there is no generic process for integrating usability evaluations into model-driven Web development processes. In this chapter, we address this issue by showing how usability evaluations can be integrated into a specific model-driven development method.

36.4 Early Usability Evaluation in Model-Driven Web Development

Currently, there are several Web development methods (e.g., WebML [Ceri et al. 2000], OO-H [Gomez et al. 2011]), environments (e.g., Teresa [Mori et al. 2004]), and languages (e.g., UsiXML [Limbourg et al. 2004]) that exploit MDE techniques to develop Web applications.

These approaches usually comprise high-level models that represent tasks that are performed by the Web application users in a way that is independent from the technology used.

The usability of a software product (e.g., a Web application) obtained as a result of a transformation process can be assessed at several stages of a model-driven Web development process. In this chapter, we suggest the use of a **Web Usability Model** that contains a set of usability attributes and metrics that

can be applied by the Web designer in the following artifacts obtained in a MDA-based Web development process:

- PIM, to inspect the different models that specify the Web application independently of platform details (e.g., screen flow diagrams, screen mock-ups, screen navigation diagrams)
- PSM, to inspect the concrete design models related to a specific platform, and
- CM, to inspect the UI generated or the Web application source code (see Figure 36.1)

In order to perform usability evaluations, the Web designer should select the set of relevant usability attributes and metrics from the Web Usability Model according to the purpose of the evaluation, the development phase, and the type of artifacts (models) to be inspected. There are some usability attributes that can be evaluated independently of the platform (at the PIM level), other attributes that can only be evaluated on a specific platform and taking into account the specific components of the Web application interface (at the PSM level), and finally some attributes that can be evaluated only in the final Web application (CM).

The usability evaluations performed at the PIM level produce a *platform-independent usability report* that provides a list of usability problems with recommendations to improve PIM (Figure 36.1—1A). Changes in PIM are reflected in CM by means of model transformations and explicit traceability between models (PIM to PSM and PSM to CM). This prevents usability problems from appearing in the Web application generated.

Evaluations performed at PSM produce a *platform-specific usability report*. If PSM does not allow a Web application with the required level of usability to be obtained, this report will suggest changes to correct the following: the PIM (Figure 36.1—2A), the transformation rules that transform PIM into PSM (Figure 36.1—2B), and/or the PSM itself (Figure 36.1—3B). Nevertheless, the evaluations at the PIM or PSM level should be done in an iterative way until these models allow the generation of a Web application with the required level of usability. This allows usability evaluations to be performed at early stages of a Web development process.

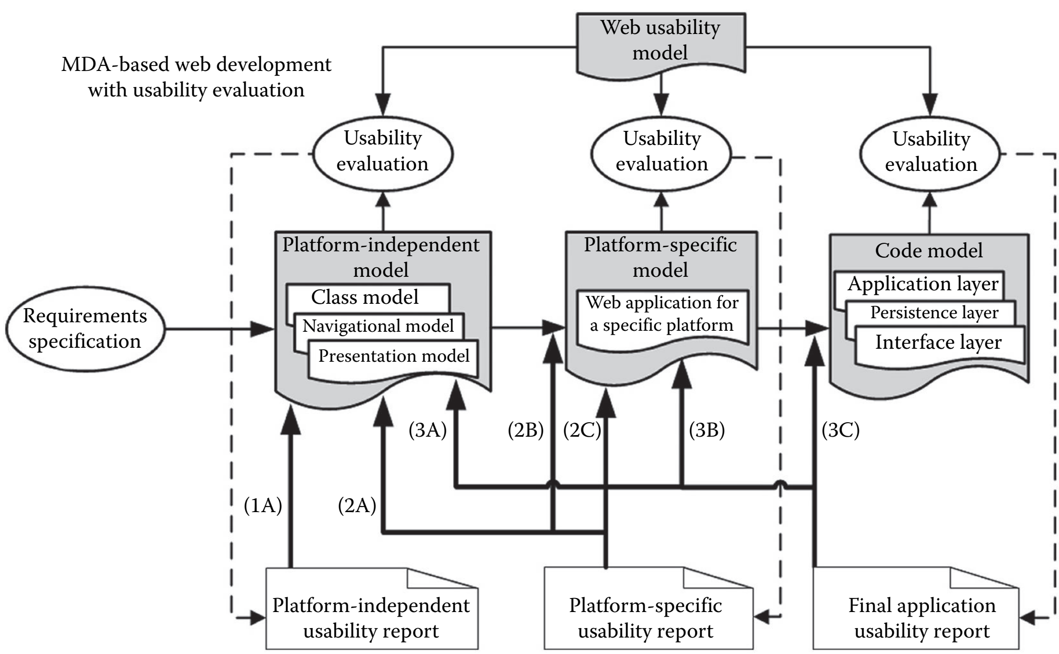

FIGURE 36.1 Integrating usability evaluations in Model-driven Web development.

Finally, evaluations performed at the CM level produce a *final application usability report*. Rather than suggesting changes to improve the final Web application, as is usual in other approaches, this usability report suggests changes to correct the PIM (Figure 36.1—3A), the PSM (Figure 36.1—3B), and/or the transformation rules that transforms the PSM into the final Web application (Figure 36.1—3C).

Our evaluation strategy is aimed at providing support to the intrinsic usability of the Web application generated by following a model-driven development process, and to the notion of usability proven by construction (Abrahão et al. 2007). Usability by construction is analogous to the concept of correctness by construction (Hall and Chapman 2002) introduced to guarantee the quality of a safety-critical system. In this development method, the authors argue that to obtain software with almost no defects (0.04% per thousand lines of code; KLOC), each step in the development method should be assessed with respect to correctness. If we can maintain proof of the correctness of a software application from its inception until its delivery, it would mean that we can prove that it is correct by construction. Similarly, if we can maintain proof of the usability of a Web application from its model specification until the source code generation, it would mean that we can prove it is usable by construction. Of course, we can only hypothesize that each model may allow a certain level of usability in the generated Web application to be reached. Therefore, we may predict the global usability of an entire Web application by estimating the relative usability levels that the models and transformations involved in a specific model-driven Web development method allow us to accomplish. We cannot prove that a Web application is totally usable (i.e., it satisfies all the usability attributes for all the users), but we can prove that it is usable at a certain level.

In the following section, we provide a brief overview of our Web usability model and show how it can be used to evaluate the usability of a Web application, early in the Web development process.

36.5 Web Usability Model

The objective of the Web usability model is to help Web designers and developers to achieve the required Web application usability level through the definition of usability characteristics and attributes, measurement of usability attributes, and evaluation of the resulting usability.

The Web usability model (Fernandez et al. 2009) is an adaptation and extension of the usability model for model-driven development processes, proposed by Abrahão and Insfran (2006). The model was adapted to be compliant with the ISO/IEC 25010 (2011) standard, also known as SQuaRE (software product quality requirements and evaluation). This standard was created for the purpose of providing a logically organized, enriched, and unified series of standards covering two main processes: software quality requirements specification and software quality evaluation. Both of these processes are supported by a software quality measurement process. SQuaRE replaces the previous ISO/IEC 9126 (2001) and ISO/IEC 14598 (1999) standards.

In order to define the Web usability model, we have paid special attention to the SQuaRE quality model division (ISO/IEC 2501n), where three different quality models are proposed: the software product quality model, the system quality in use model, and the data quality model. Together, these models provide a comprehensive set of quality characteristics relevant to a wide range of stakeholders (e.g., software developers, system integrators, contractors, and end users). In particular, the software quality model defines a set of characteristics for specifying or evaluating software product quality; the data quality model defines characteristics for specifying or evaluating the quality of data managed in software products; and the quality in use model defines characteristics for specifying or evaluating the quality of software products in a particular context of use.

The goal of the Web usability model is to extend the software quality model proposed in SQuaRE, specifically the usability characteristic, for specifying, measuring, and evaluating the usability of Web applications that are produced throughout a model-driven development process from the end user's perspective.

In the following, we introduce a brief description of the main subcharacteristics, usability attributes, and metrics of our Web usability model. The entire model, including all the subcharacteristics, usability attributes, and their associated metrics is available at http://www.dsic.upv.es/~afernandez/WebUsabilityModel.

36.5.1 Usability Attributes

SQuaRE decomposes usability into seven high-level subcharacteristics: appropriateness recognizability, learnability, operability, user error protection, accessibility, UI aesthetics, and compliance. However, these subcharacteristics are generic and need to be further broken down into measurable usability attributes. For this reason, our proposed Web usability model breaks down these subcharacteristics into other subcharacteristics and usability attributes in order to cover a set of Web usability aspects as broadly as possible. This breakdown has been done by considering the ergonomic criteria proposed by Bastien and Scapin (1993) and other usability guidelines for Web development (Lynch and Horton 2002; Leavit and Shneiderman 2006).

The first five subcharacteristics are related to user performance and can be quantified using objective metrics.

Appropriateness recognizability refers to the degree to which users can recognize whether a Web application is appropriate for their needs. In our Web usability model, this subcharacteristic was broken down by differentiating between those attributes that enable the optical *legibility* of texts and images (e.g., font size, text contrast, position of the text), and those attributes that allow information *readability*, which involves aspects of information grouping cohesiveness, information density, and pagination support. In addition, it also includes other subcharacteristics such as *familiarity*, the ease with which a user recognizes the UI components and views their interaction as natural; *workload reduction*, which is related to the reduction of user cognitive effort; *user guidance*, which is related to message availability and informative feedback in response to user actions; and *navigability*, which is related to how easily the content is accessed by the user.

Learnability refers to the degree to which a Web application facilitates learning about its employment. In our model, this subcharacteristic was broken down into other subcharacteristics such as *predictability*, which refers to the ease with which a user can determine the result of his/her future actions; *affordance*, which refers to how users can discover which actions can be performed in the next interaction steps; and *helpfulness*, which refers to the degree to which the Web application provides help when users need assistance.

Several of the aforementioned concepts were adapted from the affordance term that has been employed in the Human–Computer Interaction field in order to determine how intuitive the interaction is (Norman 1988). These subcharacteristics are of particular interest in Web applications. Users should not spend too much time learning about the Web application employment. If they feel frustrated when performing their tasks, it is likely that they may start finding other alternatives.

Operability refers to the degree to which a Web application has attributes that make it easy to operate and control. In our model, this subcharacteristic was broken down into other subcharacteristics related to the technical aspects of Web applications such as *compatibility* with other software products or external agents that may influence the proper operation of the Web application; *data management* according to the *validity of input data* and its *privacy*; *controllability* of the action execution such as cancel and undo support; *capability of adaptation* by distinguishing between *adaptability*, which is the Web application's capacity to be adapted by the user; and *adaptivity*, which is the Web application's capacity to adapt to the users' needs (i.e., the difference is in the agent of the adaptation); and *consistency* in the behavior of links and controls.

User error protection refers to the degree to which a Web application protects users against making errors. In the ISO/IEC 9126-1 (2001) standard, this subcharacteristic was implicit in the operability term. However, the ISO/IEC 25010 (SQuaRE) standard made it explicit since it is particularly important to achieve freedom from risk. In our model, this subcharacteristic was broken down into other subcharacteristics related to *error prevention* and *error recovery*.

Accessibility refers to the degree to which a Web application can be used by users with the widest range of characteristics and capabilities. Although the concept of accessibility is so broad that it may

require another specific model, the SQuaRE standard added this new subcharacteristic as an attempt to integrate usability and accessibility issues. In our model, this subcharacteristic was broken down into usability attributes by considering not only a range of human disabilities (e.g., blindness, deafness), but also temporary technical disabilities (e.g., element unavailability, device dependency). The usability attributes include *magnifier support*, which indicates that the text of a Web page must be resized regardless of the options offered by the browser for this action; *device independency*, which indicates that the content should be accessible regardless of the type of input device employed (mouse, keyboard, voice input); and *alternative text support*, which indicates that the multimedia content (images, sounds, animations) must have an alternative description to support screen readers and temporary unavailability of these elements.

The last two usability subcharacteristics are related to the perception of the end user (UI aesthetics) or evaluator (compliance) using the Web application. This perception is mainly measured using subjective metrics.

User interface aesthetics refers to the degree to which UI enables pleasing and satisfying interaction for the user. This definition evolved from the attractiveness characteristic proposed in the ISO/IEC 9126 (2001) standard. Although this subcharacteristic is clearly subjective and can be influenced by many factors in a specific context of use, it is possible to define attributes that might have a high impact on how users perceive the Web application.

In our model, this subcharacteristic was broken down into other subcharacteristics related to the *uniformity* of the elements presented in UI (e.g., font, color, position); *interface appearance customizability*, which should not be confused with the subcharacteristic *capability of adaption*, since it is not related to user needs, but to aesthetic preferences; and *degree of interactivity*, whose definition was proposed by Steuer (1992) as "the extent to which users can participate in modifying the form and content of a media environment in real time." This is a concept that has recently become increasingly important owing to collaborative environments and social networks through the Web.

Compliance refers to how consistent the Web application is with regard to rules, standards, conventions, and design guidelines employed in the Web domain. In our model, this subcharacteristic was broken down in other subcharacteristics such as the degree of fulfillment to the ISO/IEC 25010 (2011) standard and other relevant usability and Web design guidelines.

36.5.2 Usability Metrics

Once the subcharacteristics and usability attributes have been identified, metrics are associated to the measurable attributes in order to quantify them. The values obtained from the metrics (i.e., measures), and the establishment of thresholds for these values, will allow us to determine the degree to which these attributes help to achieve a usable Web application. A measure is therefore a variable to which a value is assigned as the result of measurement (ISO/IEC 9126 2001).

The metrics included in this usability model were extracted and adapted from several sources: a survey presented by Calero et al. (2005), the ISO/IEC 25010 standard (2011), and the Web design and accessibility guidelines proposed by the W3C Consortium (2008). The metrics selected for our model were mainly the ones that were theoretically and/or empirically validated. Each metric was analyzed taking into account the criteria proposed in SQuaRE (e.g., its purpose, its interpretation, its measurement method, the measured artifact, the validity evidence). If the Web metric was applied to the final UI (CM), we also analyzed the possibility of adapting it to the PIM and/or PSM levels. Due to space constraints, we have only illustrated some examples of how we defined and associated metrics to the attributes of the Web usability model. Table 36.1 shows some examples of metrics for some selected usability attributes. It also shows at what level of abstraction the metric can be applied.

TABLE 36.1 Examples of Usability Metrics

Subcharacteristic/ Usability Attribute	Metric	Definition	Model
Learnability/ Predictability/Icon/ Link Title Significance	Proportion of titles chosen suitably for each icon/title	Ratio between the total number of titles that are appropriate to the link icon they are associated and the total number of titles associated with existing links or icons (scale: $0 < X \leq 1$)	PIM, PSM, or CM
Appropriateness recognizability/User guidance/Quality of messages	Proportion of meaningful messages (error, advise, and warning messages)	Ratio of error messages explaining an error in a proper way and the total contexts where this error may occur (scale: $0 < X \leq 1$)	PIM, PSM, or CM
Appropriateness recognizability/ Navigability/ Reachability	Breadth of the internavigation (BiN)	Level of breadth in the user navigation. It represents the different paths that can be selected by the user in a certain context of the user navigation (i.e., homepage, internal sections) (scale: Integer > 0)	PIM
	Depth of the navigation (DN)	Level of depth in the user navigation. It indicates the longest navigation path (without loops), which is needed to reach any content or feature (scale: Integer > 0)	PIM

36.6 Operationalizing the Web Usability Model

The operationalization of the Web usability model consists of the instantiation of the model to be used in a specific model-driven Web development method. This is done by defining specific measurement functions (calculation formulas) for the generic metrics of the usability model, taking into account the modeling primitives of the PIMs and PSMs of the Web development method.

36.6.1 Selecting the Web Development Process

In this chapter, we use the Object-Oriented Hypermedia method—OO-H (Gómez et al. 2001) as an example of operationalization of the Web usability model. OO-H provides the semantics and notation for developing Web applications. The PIMs that represent the different concerns of a Web application are the class model, the navigational model, and the presentation model. The *class model* is UML-based and specifies the content requirements; the *navigational model* is composed of a set of navigational access diagrams (NADs) that specify the functional requirements in terms of navigational needs and users' actions; and the *presentation model* is composed of a set of abstract presentation diagrams (APDs), whose initial version is obtained by merging the former models, which are then refined in order to represent the visual properties of the final UI. The PSMs are embedded into

a model compiler, which automatically obtains the source code (CM) from the Web application by taking all the previous PIMs as input.

36.6.2 Applying the Web Usability Model in Practice

We applied the Web usability model (operationalized for the OO-H method) to a Task Manager Web application designed for controlling and monitoring the development of software projects in a software company.

A Web development project involves a series of *tasks* that are assigned to a *user*, who is a programmer in the company. For each task, the start date, the estimated end date, priority, etc. are recorded. The project manager organizes the tasks in folders according to certain criteria: pending tasks, critical tasks, and so on. Additionally, it is possible to attach external *files* to a task (e.g., requirements documents, models, code). Programmers can also add *comments* to the tasks and send *messages* to other programmers. Every day, programmers can generate a report (*Daily Report*), including information related to the tasks they are working on. Finally, the customers (i.e., stakeholders) of the project are recorded as *Contacts* in the Web application.

Due to space constraints, we focus only on an excerpt of the Task Manager Web application: the user access to the application, the task management, and the registration of customer's (contact's) functionalities. Figure 36.2a shows a fragment of the NAD that represents the user access to the application, whereas Figure 36.2b shows the abstract presentation model generated from the class model and the navigational model.

The NAD has a unique *entry point* that indicates the starting point of the navigation process. This diagram is composed of a set of navigational elements that can be specialized as navigational nodes or navigational links. A *navigational node* represents a view in the UML class diagram. A navigational node can be a navigational target, a navigational class, or a collection. A *navigational target* groups elements of the model (i.e., navigational classes, navigational links, and collections) that collaborate in the coverage of a user navigational requirement. A *navigational class* represents a view over a set of attributes (navigational attributes) and operations (navigational operations) of a class from the UML class diagram. A *collection* is a hierarchical structure that groups a set of navigational links. Navigational links define the navigation paths that the user can follow through UI. There are two types of links: *source links* when new information is shown in the same view (depicted as an empty arrow); and *target links* when new information is shown in another view (depicted as a filled arrow).

In Figure 36.2a, NAD shows the programmer (*User*) accessing the Web application, starting at the *User Entry Point*. The next node in the diagram is the *User* navigational class, which corresponds to a data entry form through which the programmer can log into the application. This process requires *profile* information, a *username*, and a *password*. If the user exists, which is represented by the navigational link *LI4*, the system displays a menu (*restricted home*) with links to each of the three possible navigational destinations (*Tasks*, *Contacts*, and *Reports*). If the user does not exist, the system shows an error message (*LI2*) returning to the initial data entry form (LI6). The *restricted home* menu is represented by a collection node, which includes the navigational links LI63, LI19, LI75, and LI28. In addition, the label *connected as* shows the log in information (LI92).

In Figure 36.2b, the abstract presentation model shows the three abstract pages generated from the previous NAD. The *User* navigational class produces a Web page showing the abstract access to the application (see Figure 36.2—b1). The navigational link *LI2* generates the error message represented by the *error* collection in a different abstract Web page (see Figure 36.2—b2). Finally, the *restricted home* collection, which is accessed through the navigational link *LI4*, generates the user's home page in a different abstract Web page (see Figure 36.2—b3), representing the possible navigational targets (*Tasks*, *Reports*, and *Contacts*). However, as the label *connected as,* represented by the navigational link *LI96*, is a *source link* (empty arrow), the log in information is shown in the same user's generated home page (see Figure 36.2—b3).

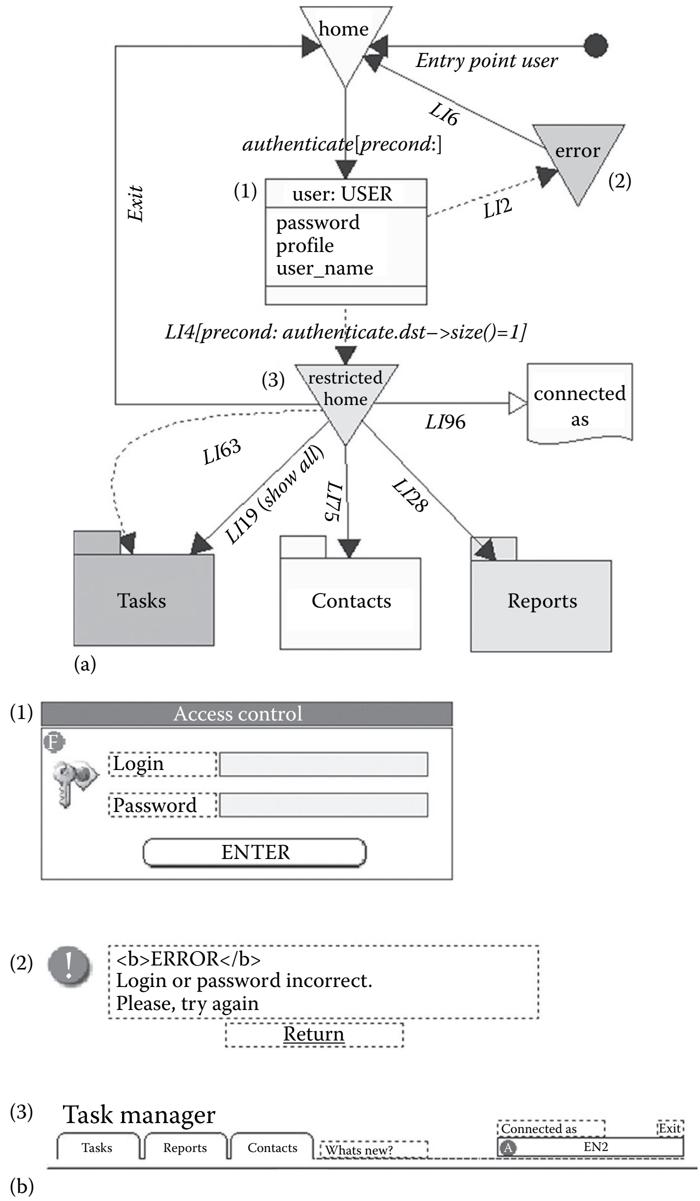

FIGURE 36.2 (a) First level NAD and (b) its associated APD for the Task Manager Web application.

The following usability metrics can be applied to the Navigational Model in Figure 36.2a:

- *Breadth of the internavigation (see Table 36.1)*: This metric can only be operationalized in those NADs that represent the first navigation level (i.e., internavigation). The calculation formula to be applied is *BiN (NAD) = Number of output target links from collections connected to navigational targets*. The thresholds* defined for the metric are [BiN = 0]: critical usability problem; [1 ≤ BiN ≤ 9]: no usability problem; [10 ≤ BiN ≤ 14]: low usability problem; and [15 ≤ BiN ≤ 19]: medium

* These thresholds were established considering hypertext research works such as those of Botafogo et al. (1992), and usability guidelines such as those of Leavit and Shneiderman (2006) and Lynch and Horton (2002).

usability problem. Therefore, the breadth of the internavigation for NAD shown in Figure 36.2a is 4 since there are four first-level navigational targets (i.e., Home, Tasks, Contacts, and Reports). This signifies that no usability problem was detected.

- *Depth of the navigation (see Table 36.1)*: This metric considers the number of navigation steps from the longest navigation path. Therefore, the formula to be applied is *DN (NAD) = Number of navigation steps from the longest navigation path,* where "navigation step" is when a target link exists between two nodes and "longest navigation path" is the path with the greatest number of navigation steps, which begins in the first navigational class or collection where navigation starts, and which ends in the last navigational class or service link, from which it is not possible to reach another previously visited modeling primitive. The thresholds* defined for this metric are [$1 \leq$ DN ≤ 4]: no usability problem; [$5 \leq$ DN ≤ 7]: low usability problem; [$8 \leq$ DN ≤ 10]: medium usability problem; and [DN ≥ 10]: critical usability problem. Therefore, the depth of the navigation for the NAD shown in Figure 36.2a is 2, because the length of the longest navigational path between the root of the navigational map and its leaves (Tasks, Contacts, and Reports—navigational targets) passes through two navigational links. This means that no usability problem was detected since obtained values are within the threshold [$1 \leq$ BaN ≤ 9].

The values obtained through these metrics are of great relevance to the navigability of a Web application. If the navigational map of the Web application is too narrow and deep, users may have to click too many times and navigate through several levels to find what they are looking for. However, if the navigational map is too wide and shallow, users may be overwhelmed due to the excessive amount of information they can access. In this context, for large Web applications that have a hierarchical structure, the recommended value is usually a *depth* of less than 5 levels and an *amplitude* of less than 9 levels. Since the navigational map of our Task Manager Web application obtains values below these thresholds, this Web application has a good navigability.

Regarding the abstract presentation model in Figure 36.2b, the following metrics, which are closer to the final UI, may be applied:

- *Proportion of meaningful messages (see Table 36.1)*: There is only one error message "Log in or password incorrect. Please try again." As the message properly explains what is wrong, the value of the metric is 1/1 = 1. This result is very positive because values closer to 1 indicate that the error messages are very significant, thus guiding the user toward the correct use of the Web application.
- *Proportion of titles chosen suitably for each icon/title (see Table 36.1)*: As an example, we focus on the titles of the links of the APD shown in Figure 36.2b: *Enter, Return, What's new,* and *Exit*. Since all the titles make us intuitively predict the target of these links, the value for this metric is 4/4 = 1. This result is very positive because values closer to 1 indicate that the selected titles are appropriate to the icons or links, allowing the user to predict what actions will take place.

Obviously, these metrics can be applied to each one of the abstract Web pages of an application to determine to which extent they provide proper labels and meaningful error messages. In this running example, we have used only a fragment of the Task Manager Web application. However, the Web usability model is fully applicable to a complete Web application that has been developed following a MDE approach. Although the usability model has been operationalized in OO-H, it can also be used with other model-driven Web development methods, for example, WebML (Ceri et al. 2000) or UWE (Kraus et al. 2006). The key is to relate the attributes of the Web usability model with the modeling primitives of the PIMs, PSMs, or the final code of the Web application. To establish these relationships, it is essential to understand the purpose of the generic usability metrics (to understand what concepts they are intended to measure) and then to identify which elements of the models provide the semantics needed to support them.

* These thresholds were established considering hypertext research works such as those of Botafogo et al. (1992), and usability guidelines such as those of Leavit and Shneiderman (2006) and Lynch and Horton (2002).

36.7 Summary

This chapter introduced a usability inspection strategy that can be integrated into specific model-driven Web development methods to produce highly usable Web applications. This strategy relies on a usability model that has been developed specifically for the Web domain and which is aligned with the SQuaRE standard to allow the iterative evaluation and improvement of the usability of Web-based applications at the design level. Therefore, this strategy does not only allow us to perform usability evaluations when the Web application is completed, but also during the early stages of its development in order to provide feedback to the analysis and design stages.

The inherent features of model-driven development (e.g., well-defined models and the traceability between models and source code established by model transformations) provide a suitable context in which to perform usability evaluations. This is due to the fact that the usability problems that may appear in the final Web application can be detected early and corrected at the model level. The model-driven development also allows the automation of common usability evaluation tasks that have traditionally been performed by hand (e.g., generating usability reports that include recommendations for improvement).

From a practical point of view, our usability inspection strategy enables the development of more usable Web-based applications by construction, meaning that each step of the Web development method (PIM, PSM, Code) satisfies a certain level of usability, thereby reducing the effort of fixing usability problems during the maintenance phase. This is in line with research efforts in the computer science community toward raising the level of abstraction not only of the artifacts used in the development process but also in the development process itself.

In this context, there are several open research challenges, mainly due to the highly evolving nature of the Internet and Web applications, and also because of the concept of usability. Although there are some underlying usability concepts that may remain immutable (e.g., the concept of navigation), there are new devices, platforms, services, domains, technologies, and user expectations that must be taken into consideration when performing usability inspections. This may lead us to determine the families of Web applications and to identify the most relevant usability attributes for these families. In addition, there is a need for the study of aggregation mechanisms to merge values from metrics in order to provide scores for usability attributes that will allow different Web applications from the same family to be compared.

36.8 Future Research Opportunities

The challenge of developing more usable Web applications has promoted the emergence of a large number of usability evaluation methods. However, most of these methods only consider usability evaluations during the last stages of the Web development process. Works such as those of Juristo et al. (2007) claim that usability evaluations should also be performed during the early stages of the Web development process in order to improve user experience and decrease maintenance costs.

This is in line with the results of a systematic review that we performed to investigate which usability evaluation methods have been used to evaluate Web artifacts and how they were employed (Fernández et al. 2011). The study suggests several areas for further research, such as the need for usability evaluation methods that can be applied during the early stages of the Web development process, methods that evaluate different usability aspects depending on the underlying definition of the usability concept, the need for evaluation methods that provide explicit feedback or suggestions to improve Web artifacts created during the process, and guidance for Web developers on how the usability evaluation methods can be properly integrated at relevant points of a Web development process.

Glossary

Model-driven engineering (MDE): A software development approach that focuses on creating and exploiting domain models (abstract representations of the knowledge and activities that govern a particular application domain), rather than on the computing (or algorithmic) concepts.

Platform-independent model (PIM): A view of a system that focuses on the operation of a system while hiding the details necessary for a particular platform.

Platform-specific model (PSM): A view of a system from the platform-specific point. A PSM combines the specifications in the PIM with the details that specify how that system uses a particular type of platform.

Usability by construction: Proof of the usability of a software application from its model specification to its generated final code.

Usability problem: The problem that users will experience in their own environment, which affects their progress toward goals and their satisfaction.

Transforming HCI: The Art, Science, and Business of User Experience Design

William M. Gribbons
Bentley University

Roland Hübscher
Bentley University

Over the past 30 years, our approach to designing technology has evolved in response to a dramatically changing marketplace. Many of these changes were a reaction to an ever-increasing shift in people's expectations for the use of technology. The result is a sure-to-continue cycle where technological innovation and better design elevate user expectations, further driving future design and innovation. In response to these changes, the human computer interaction (HCI) discipline must reexamine past research and professional practices and make appropriate accommodations to better serve new technologies, conditions, and market pressures. The need for this chapter should not be viewed as a failure

of past efforts. Instead, this is simply a continuation of the discipline's ongoing evolution from industrial psychology to human factors and then to HCI.

This chapter examines changes in the marketplace for technology products over the past 30 years and proposes transforming our traditional HCI framework based on an expanded perspective offered by user experience (UX) research and design. This chapter will begin by examining the conditions that drove this change and then offer a more detailed review of the human elements relevant to emerging technologies as well as research necessary to meet the more sophisticated demands of the evolving technology and marketplace. The chapter concludes by proposing a process that supports each of these elements, thereby increasing the probability of a successful product design.

37.1 Changing Market Conditions

If the HCI discipline has learned anything over the last three decades, it is that we can rarely force change without the need first existing in the user community. Of course, there will always be an exception for extraordinary technological breakthroughs, but even in these cases you can typically trace the success of a given innovation to the fulfillment of an unmet human need or the delivery of unique value.

Factors influencing the success of new technology offerings have evolved dramatically over the past three decades. During the 1980s and 1990s, success was determined almost exclusively by the power, stability, and functionality of new technologies. This was the correct strategy at the time, given technology delivered value by lessening the drudgery of a previously manual activity or through previously unobtainable levels of productivity, quality, or safety. However, the competitive advantage offered by this focus alone diminished over time. In response to pressures from the marketplace, the technology community continued to produce innovative technologies with an ever-increasing focus on the goals, values, and abilities of the end user (Raskin 2000). Along this journey, the HCI discipline shifted from a role of enhancing design late in development, to influencing the early design, and finally to a strategic role of defining the design space. In an issue of *Interactions* dedicated to reimagining HCI, Panu Korhonen (2011) of Nokia captured this transformation of the profession nicely:

> In the early days, HCI people were told "Please evaluate our interface and make it easy to use." That gave way to "Please help us design this user interface so that it is easy to use." That in turn, led to a request "Please help us find what the users really need so that we know how to design this user interface." And now, the engineers are pleading with us "to look at this area of life and find us something interesting."

Increasingly, a deep and systematic focus on the user is emerging as a key competitive differentiator in the most progressive product development groups and for leading business service providers, particularly for those operating in hypercompetitive markets.

Naturally, a close consideration of the user in product design does not minimize the importance of the technological components of product development; it simply suggests that those qualities alone are rarely sufficient to ensure success in a world where powerful technology has become the norm. Figure 37.1 depicts the evolution of product design over the past three decades from the early days of a pure engineering focus to the one focused on usability and now the UX. In this model, each stage is a prerequisite for the next. Accompanying that shift is a progressively deeper integration of the UX strategy in the development and business culture. In the 1980s, the success of a product was determined almost exclusively by the power, performance, functionality, and its ability to enable work efficiently. Once these critically important goals were met and became commonplace, users came to expect this as a standard and then demanded that a given technology become more useful and usable (Veryzer and Borja de Mozota 2005). Usability was soon defined by ease-of-learning, transfer-of-learning, and a close mapping to users' abilities and usefulness focused on users' goals and what they valued (Dumas and Redish 1999). We then saw the pattern repeat again. Once usability and usefulness became best practices in the marketplace, users then demanded a

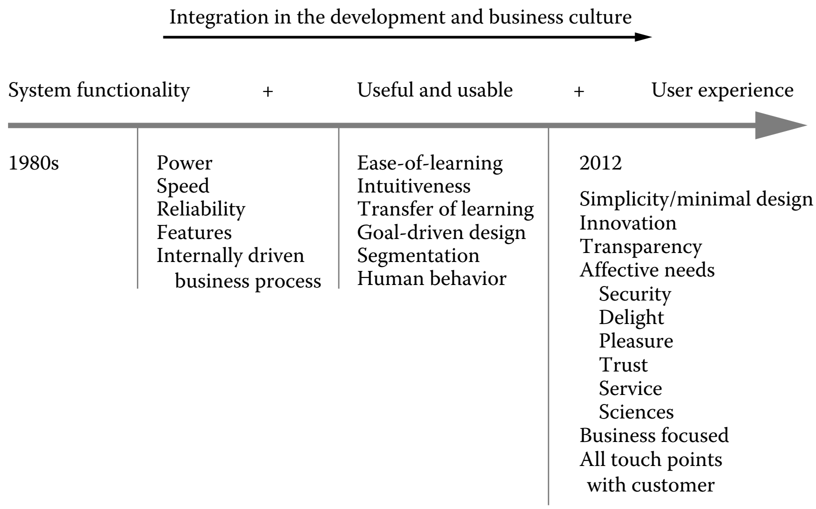

FIGURE 37.1 Evolution of product design over the past three decades.

deeper, far-reaching, and carefully orchestrated UX. A component of that stage was the move toward minimal design (simplicity) as seen in the lean start-up movement (Maeda 2006; Ries 2011), reducing the load imposed by the system, and by focusing on those aspects of the product that users value most (Dixon et al. 2010). This approach to product design stands in stark contrast to the bloated, feature-rich development strategy of the past where we looked to incremental feature enhancements to sustain a product through the market life cycle. That was a time characterized by an incomplete understanding of the requirements of the user community leaving us with no alternative but "just-in-case-design." Finally, UX considers the affective component of the experience as well as how the experience can be extended beyond the technology itself to every touchpoint with the customer (Khalid and Helander 2006; Norman 2003; Walters 2011).

Three dominant market forces contributed significantly to this evolution:

1. The evolving expectations of users
2. The expanding diversity of the user community
3. The growing application of technology in all aspects of our lives

37.1.1 Evolving Expectations of Users

A key characteristic of human behavior is that our expectations evolve based on a continually changing base of experiences. Each new experience that delivers greater value, pleasure, performance, or efficiency creates a new and elevated expectation. This behavior governs all aspects of our human experience (Eysenck 2012). In the case of technology, this change is partially a product of constantly improving technology. In a changing marketplace, user expectations evolve based on the enabling qualities of each new technology, interaction design potential, and with each increase in product usability. In short, what was once a successful "standard" of excellence in the 1990s is no longer acceptable to today's more demanding user, a trajectory that will continue in perpetuity. The lesson learned in the marketplace is clear: technology producers who recognize and respond in a timely fashion to this new product life cycle will thrive, while those who do not will fail (Christenson 1997; Martin 2009).

37.1.2 Expanding Diversity of the User Community

Further contributing to the changing marketplace is the significantly expanding diversity of users (Langdon et al. 2007). Gone are the days when we designed for a homogeneous community of well-educated, highly motivated, technologically savvy, and adaptable users. In the past, this community was

required to "bend" to the demands of powerful systems that were often misaligned with their needs and abilities. Fortunately, this population was willing and able to make the required accommodations based on highly developed abilities and motivated by the value derived from the system. Today, the system must increasingly bend, to varying degrees based on context, to the user while still serving the larger purpose of the system. Today's user might be less technologically savvy, illiterate, unmotivated, cognitively or physically disabled, elderly, or living in a developing country. The topic of universal accessibility is addressed later in this chapter. User experience for "all" has raised the art and science of system and interaction design to previously unknown levels of sophistication.

37.1.3 Growing Integration of Technology in All Aspects of Our Lives

Finally, users were more capable and willing to "bend" when a limited number of technologies required this accommodation. This too has changed. In many areas of the global marketplace, technology has "penetrated" each and every aspect of our lives: our homes, communication, social communities, transportation systems, work, education, entertainment, commerce, government, and healthcare.

Our understanding of the human information processing system has long confirmed that we possess finite resources for interacting with our environment (Wickens and Hollands 1999).

As ubiquitous technology places ever-increasing demands on people, their capacity to manage this workload is challenged. If technology is to continue enriching and improving our lives, new technology must impose a lighter load by more closely aligning with the values and abilities of the user. This clearly requires designers to develop an increasingly deeper understanding of user's interactions with technology and the alignment of that interaction with the strengths and limitations imposed by the human information processing system.

37.2 Common Framework

No technology sector is insulated from these market forces. Separately, the pressures of this change have been felt in business information technology, commercial software/hardware, consumer electronics, government systems, games, social media, healthcare, entertainment, and transportation. Rather than approaching each of these sectors as a *unique* challenge requiring a *unique* framework for understanding users, a common approach can be identified and appropriate support found in the merged UX and HCI disciplines. A fractured strategy, focused on individual sectors, will ultimately weaken the larger cause and fail to fully leverage a shared research agenda.

Moving forward, the merged HCI–UX discipline can take great comfort in knowing that the traditional behavioral and perceptual foundations of the HCI discipline continue to serve us well. However, the range of behaviors and perceptual inputs will expand, and the complexity of the interaction across subvariables will increase. This is a challenge the discipline has met in response to past innovation. Expansion of the research agenda is particularly necessary in the social, emotional, aesthetic, and cultural elements of the UX. On the interaction design front, we will continue our progress to full integration of multimodal interaction—audible, haptic, and auditory (Heim 2007). Here, we must examine how a particular mode best supports an interaction requirement and manage the complex and difficult-to-predict interactions across these interaction modes.

While we work to identify a common research and practice framework to accommodate diverse industries, it remains useful to recognize that unique challenges do exist within industry sectors. For example, making the case for focusing on the customer is relatively clear in the commercial marketplace for hardware, software, and consumer electronics. More challenging is the case for business IT and government systems—these are difficult, but not impossible. In the case of IT, our past focus on business rules, work processes, productivity, and the enabling qualities of the technology often occurred at the expense of the users responsible for implementing, supporting, and using the system (Babaian et al. 2010). This often resulted in high failure rates, partial implementations, slow and incomplete adoption of

the system, and unexpectedly high total life cycle costs. In the case of government systems, we have witnessed a slow and steady march to making government and healthcare available to the public through information and communication technologies (Becker 2005; McClelland 2012; Sainfort et al. 2012). Here too, acceptance and use of these systems is critically dependent on the ease of use and quality of the UX. E-government and e-health possess tremendous potential for improving people's lives; however, we will only realize this potential when the supporting systems are accessible to the larger population (Borycki and Kushniruk 2005; Croll and Croll 2007; Gribbons 2012). Any solution focused narrowly on the enabling ICT without a clear consideration of usability and the UX is likely to fail.

37.3 From HCI to UX

Building on a traditional HCI foundation, the UX promotes the careful alignment of human behaviors, needs, and abilities with the core value delivered through a product or service. Depending on context, this experience may have psychological, social, cultural, physiological, and emotional components—most likely, a combination of all five. In contrast to traditional HCI, UX broadens the scope of the human experience considered in interaction design including the emotional, social, internationalization, and accessibility. Similar to traditional HCI, the UX discipline defines the optimum experience through the detailed study and assessment of the user in the appropriate use environment. Even here we see a need to move from less formal modes of inquiry to more rigorous methods such as ethnographic inquiry. Ultimately, UX design applies these theoretical principles and research practices with a goal of exercising greater control over users' response to a design. In other words, they strive to produce predictable outcomes for the system consistent with a set of desirable, defined, and measurable goals.

37.4 UX and a Holistic View of Product Design

UX also embraces a more holistic view of product design. In the past, user requirements were often defined in a vacuum, most often assuming ideal conditions. Learning from the shortcomings of past practice, UX identifies, manages, and accommodates the various business and development forces in play that might necessarily or needlessly influence the finished product design and eventually compromise the UX.

As depicted in Figure 37.2, user goals are compared to business goals, and where the conflict between these two cannot be resolved, tensions are documented and their effects minimized in the design.

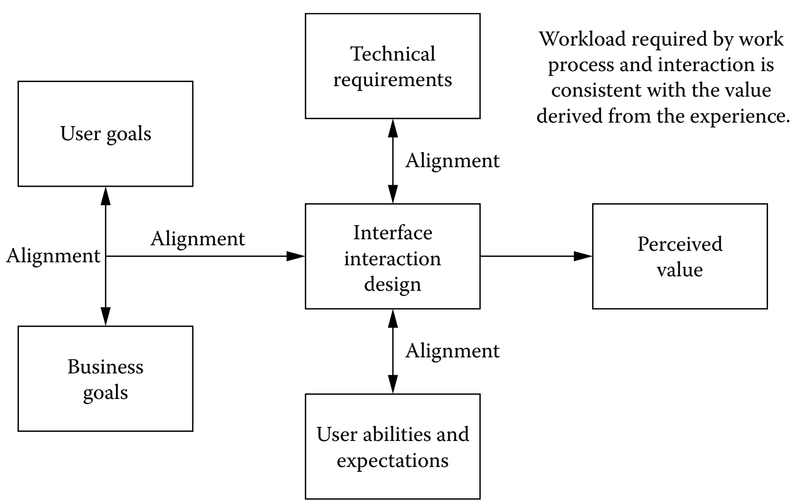

FIGURE 37.2 UX and product design model.

As goals are moved to implementation, the UX practitioner then assesses the impact of technical and regulatory requirements on the UX. Given that the regulatory requirements must be supported, tensions between those requirements and the abilities and expectations of the user must be noted and accommodated. Under ideal circumstances, technical requirements would specify leading-edge technologies that align with and support the user's expectations and abilities. In many cases—sometimes driven by business goals—older technologies are employed, existing code is repurposed, and requirements for compatibility with other systems drive technical requirements. Tensions then arise with users' expectations and abilities. In the final analysis, UX design recognizes that unavoidable tensions can exist within a system; yet, it can still produce acceptable results if these tensions are properly managed and when the perceived value of the system exceeds the workload required by the suboptimum interaction experience. The converse is true for a misaligned system that delivers marginal value at high interaction costs.

37.5 UX Meets Business

In contrast to traditional views of HCI, UX balances business and user needs given its growing contribution to competitive differentiation. As noted earlier, the "differentiation value" of the UX has grown as many technologies and business services become commoditized in hypercompetitive markets (Pine and Gilmore 1999). In this new role, we must deeply integrate UX theories and practices in the development process as well as in the strategic framing, pricing, and competitive positioning of products and services. Finally, we must recognize the contributions of UX in nontechnology-based areas such as process design, customer support, or invoicing—further expanding the influence of the discipline.

In the past, one would rarely hear discussions of HCI's contribution within the ranks of senior executives or see HCI play a prominent role in the producing organization's marketing or product positioning. This is not the case with UX where we now find the discipline prominently displayed in competitive positioning and advertising—in the most extreme cases, the experience becomes the brand as seen in companies such as Apple, Facebook, and Amazon. Recognizing that strategic value, many development organizations have subsequently promoted UX professionals to senior executive ranks.

User experience's journey up the value chain in the business organization could not have come at a more opportune time. Paralleling the advancement of the UX profession is a growing need in business to continuously innovate products, services, and processes as well as innovation's critical role in sustaining long-term competitive advantage. While the business community often frames this discussion in the context of "design thinking," a careful examination of that "movement" reveals that many of its foundational concepts and practices are consistent with UX theory and practice. Roger Martin (2009), Dean of the Rotman School of Management at the University of Toronto, builds a compelling case for the value of design thinking in his book *The Design of Business*, characterizing this strategy as the next competitive advantage in the business world. Tim Brown (2009), CEO and President of IDEO, makes an equally compelling case for design thinking in his book *Change by Design*.

For more than 30 years, the UX discipline and its HCI predecessor advanced many of the foundational principles and practices found at the core of the design thinking movement.

We also see the convergence of business and UX in an emerging line of marketing research that examines the features of technology that drive a purchase or adoption decision. Emerging research in this area suggests that the features that drive a purchase decision are often the very same features that compromise the user's experience with the purchased product (George Group 2012; Rust et al. 2006; Zhao et al. 2012). UX professionals must work closely with their marketing colleagues to strike an artful balance between driving the purchase decision while fostering a positive long-term UX. Examining the tension between the behaviors that drive adoption/purchase decisions and those that determine long-term satisfaction with the product's use is an important addition to the UX research agenda.

Each of these changes—UX to business and business to UX—is a recognition of the previously discussed market conditions and a reflection of the fact that while technological innovation alone may be adequate for the initial success of a product it is rarely adequate to sustain long-term success in the marketplace.

37.6 Ethics and Unintended Consequences

As the UX discipline extends its reach beyond the early challenges of enabling work, improving usability, extending productivity, and expanding interaction design capabilities, the discipline is increasingly likely to encounter far more complex and unexpected issues resulting from people's use of technology and a deeper understanding of the depth and breadth of the UX. Clearly, new technologies have always produced unintended secondary consequences as noted by historians (Kranzberg and Pursell 1967). What has changed is the pervasiveness of these consequences and their severity. As a consequence, the UX discipline must consider and debate its contribution to and responsibility for the unattended consequences of new technologies, some of them with a clear ethical dimension. Issues examined within this section include

- Accommodating and influencing user's behavior
- Human cost of automation and devaluing work
- Deskilling
- Erosion of privacy
- Dangers of distraction

While fueling an ongoing discussion within the profession, these issues will also contribute to the discipline's research agenda moving forward.

37.6.1 Accommodating and Influencing User's Behavior

As we deepen our understanding of human behavior, we have increased our ability to deliberately influence and control users' behavior through system design. While design has always had this effect to some degree, the implications moving forward are potentially more far-reaching and significant based on the potential of emerging technologies. A case in point is the growing desire to subtly alter the irrational behavior regularly exhibited by people.

Ariely (2008) demonstrates convincingly the endless number of occasions where people make poor choices in critical aspects of their lives, thus challenging the traditional view that people exhibit logical, rational behavior in important situations. Ariely suggests that this irrational behavior is so predictable that we need to question our traditional view of what constitutes rational behavior.

Contributing to this behavior are various emotions and biases that direct our actions in irrational ways. In response to the predictability of this suboptimum behavior, some suggest that we should direct this behavior to a more positive and beneficial outcome. Sunstein and Thaler (2008) correctly propose, based on a deep understanding of human behavior, that we can design "choice environments" that make it "easier" for people to choose what is best for them, their families, and society, thereby minimizing the possibility of irrational responses, biases, and emotions. The authors are careful to frame this proposal in a positive fashion with careful safeguards to protect one's freedom of choice while producing more positive outcomes in terms of health, financial security, and personal happiness.

Such thinking has interesting implications for UX design since it would be the designer who frames the experience—both the interaction and the information design—to produce an outcome some authority deems "in the best interest of the user." In an ideal world, this all seems well and good if there were some objective measures of which outcome was in the best interest of the user. Despite the designer's best intentions, they must be cognizant that the selections they make in creating the optimum "choice environment" are subject to the very same biases they are trying to minimize and that these biases operate outside of their conscious control. In the worst case, UX designers must also consider that for every product with the "best intention" there will be another that deliberately "nudges" the user to ends not in the user's best interest, but to those of a different stakeholder.

This creates a vexing ethical conundrum for UX designers. On the one hand, they recognize that human behavior often results in suboptimum choices and actions. On the other hand, they recognize

that they have the potential, through design, to affect that behavior in other ways—positive and negative. At the very least, this begs the question: "how do UX professionals define their ethical responsibilities as they subconsciously influence users' decisions or actions?" The case of producing negative outcomes is clear, but less clear is who determines what is "positive" and the recognition that the line between the two is often not well defined.

As the UX profession gains a deeper understanding of human behavior and its implication for interaction design, they have begun to question past practices. For example, system designers typically create products assuming a rational user. Based on the goal of supporting a logical, rational response, they conduct research to determine appropriate information support, an optimum sequence of actions, optimum feedback, and ideal outcomes. This research is likely to validate the initial assumptions because the research activity engaged the conscious, "rational side" of the user's mind. This information is then captured as user requirements and scenarios that are implemented and supported through the system design. The designer is then surprised when the user—now guided by natural, emotional behaviors outside their conscious control—interacts with the system in an unexpected, suboptimum fashion (Kahneman 2011). Traditionally, interaction designers would characterize this behavior as "carelessness," "laziness," or "human error." This raises yet another challenging question: can the UX designer predict and accommodate this behavior without falling into the manipulation trap described previously?

37.6.2 Human Cost of Automation and Devaluing Work

So much of the HCI discipline's early effort was driven by the desire to improve human performance and productivity while reducing errors. Few questioned the value of these gains—gains achieved by optimizing the system design, augmenting human ability, and automating various components of the supported activity. At the same time, some in the discipline have examined the human cost of automation (Parasuraman and Mouloua 1996), a discussion not limited to the loss of jobs. While most applaud automation when it eliminates dangerous, repetitive, or tedious work, other forms of automation often come at the cost of diminishing the intellectual and emotional value of that work. In some cases, such as the level of automation found in fast food restaurants or warehouse fulfillment centers (McClelland 2012), it has reached a state where work is nearly dehumanized, opportunities for worker growth diminished, and the value of rewarding work stripped away. Given the UX professional's role in designing that experience, what responsibility does the profession have for these undesirable outcomes?

37.6.3 Deskilling

Over the past two decades, there have been tremendous advances in the development of powerful intelligent support systems that augment human intelligence in the most demanding environments. For example, modern aircraft have grown so complex that pilots can no longer operate the aircraft without an "intelligent" assistant, particularly in situations of catastrophic failure. The positive benefits of this technology enable the use of sophisticated technologies and improve safety (Charette 2010). At the same time, the UX research agenda must examine the possible "deskilling" effects of automation on the operator and evaluate the ability and need of the operator to respond in the absence of intelligent support (Zuboff 1982). Similar discussions are also present in the medical community where medical professionals, including doctors, are increasingly employing powerful diagnostic systems with the same benefits and concerns raised in aviation (Berner 2008). Moving forward, UX professionals must go beyond the positive, intended outcomes of the technologies they design and consider the unattended consequences of new technologies for the user. In some cases, the gains will clearly outweigh the negative consequences and the loss accepted. In others, the level of support and automation might warrant reconsideration. Whatever be the outcome, it is critical that UX designers initiate this conversation.

37.6.4 Erosion of Privacy

The case of remote monitoring technologies for the elderly and children provides another interesting case of unintended consequences. As life expectancies increase in many societies, so too has the attention directed to improving the quality of life for this population. With the best of intentions, technologies have been developed and employed to remotely monitor the daily activities of independently living elders—their every movement, what and how much they eat, and when they take their prescribed medications. Such advances have enabled a high-value goal of elders to live independently in a place of their choosing. While the benefits are clear, an unintended consequence is the loss of privacy and dignity—also highly valued by the population—as a consequence of monitoring beyond their control. Similar technologies are also employed by parents to monitor their children's every movement, how fast they are driving, and their location at any moment in time. Product designers create each of these technologies focused on the positive intended consequence; however, each technology is accompanied by an unintended outcome of the loss of privacy, dignity, and perhaps independence.

37.6.5 Dangers of Distraction

Finally, the convergence of technologies in many use environments produces an attention load that threatens the very limits of human capabilities. A case in point is the ever-increasing integration of communication, navigation, and entertainment technologies in automotive design. While these technologies deliver unquestionable value and pleasure to the driver and passenger, they divide the operator's attention in ways that distract from the primary driving task—a situation creating life-threatening situations for all who travel our roads and highways (Beede and Kass 2006). What responsibility do UX professionals have in situations such as these where we might focus on only the positive outcome of a technology and either intentionally or inadvertently fail to recognize possible negative consequences? The ever-increasing likelihood of distraction and its consequences should become an area of intense focus in the discipline's research agenda.

At the end of the day, UX professionals must increasingly consider where their responsibilities lie, with the product organization that reaps financial gains from the technology they sell or with the user who will suffer possible negative or potentially life-threatening consequences of these products. Because the occurrence of these events has become more frequent and the consequences more severe, the profession can no longer avoid this question.

37.7 UX for All Users

Moving forward, the UX discipline must embrace all users, not simply those of a certain ability, economic class, or region of the world. The discipline must avoid the past narrow focus on capable, economically desirable populations and instead address the needs of an increasingly diverse user community, for example, those of a poor illiterate farmer in a developing nation using ICTs to better manage the planting, harvesting, and marketing of his crops. A serious mistake was made in the past where the discipline focused on an artificial designation of the "typical user" and "typical behavior" and relegated accessibility and internationalization to the periphery—factors the designer addresses once the core produced is created. This approach communicated that each of these activities was optional and virtually eliminated them from common practice. Instead, we must seamlessly integrate universal design (Shneiderman 2000) and internationalization (Marcus and Gould 2012) into the core design in all but the most regionalized product directed to homogenous populations.

It is easy to understand why the previous approach was adopted. First, the foundational psychological research focused primarily on western subjects. Second, the cognitive/perceptual research most often

assumed an optimally functioning individual. Third, the early marketplace for technology and the HCI profession's connection to this marketplace initiated and perhaps perpetuated this bias. Because technology now touches users of unimaginable diversity in every corner of the world, the discipline's past approach is no longer acceptable either in theory or practice.

37.7.1 Global

The UX movement must become a movement for all users, not simply an experience based on the values, beliefs, and behaviors of one geographic region or the other. The discipline has long understood that the sensory component of the human experience is the same in almost every practical way. In other words, the register of colors, sounds, and touch sensations is essentially universal (Ware 2000). In contrast, how these signals are encoded and acted upon during higher levels of cognitive processing will vary across cultures. In some cases, there will be significant differences (Matsumoto and Juang 2008). Over the past several decades, research in the field of intercultural psychology has offered invaluable insight into cultural difference in areas such as communication, creative thinking (Paletz and Peng 2008), collaboration, learning (Li 2003), evaluation, decision making (Briley et al. 2000), and the like (Berry et al. 2011; Kamppuri et al. 2006). This research has implications not only for the internationalization of the interaction experience but also for the research methods we use to study users and how we interpret those findings.

37.7.2 Universal Design

As discussed earlier, a distinctive characteristic of today's technology marketplace is the incredible diversity of the user community, with an ever-increasing likelihood that the user might be illiterate, cognitively disabled (Gribbons 2012), physically handicapped (Jacko et al. 2012), or elderly (Czaja and Lee 2008). The UX academy and profession must be at the vanguard of creating an inclusive environment where all users fully realize the remarkable benefits of technology. This is especially important given technology is interwoven into the very fabric of our lives at home, work, civic engagement, wellness, and play. For years, the HCI profession led the crusade for addressing the needs of special populations, first those with physical disabilities, then the unique needs of the elderly, and finally those with cognitive disabilities. This crusade eventually coalesced under the universal design moniker. The UX movement must advance this cause by more deeply and seamlessly integrating universal design principles into the core tenets of the discipline.

The first principle of universal design dictates "provide the same means of use for all users: identical if possible—equivalent when not" (Story 1998). When executed properly, the required accommodations are transparently embedded in the system, interface, and interaction design and are unlikely to affect development costs or create obstacles for the nondisabled. It is widely accepted in the accessibility community that the required accommodations typically improve the usability of the product for every user (Dickinson et al. 2003; Gribbons 2012). If all people are to have equal opportunities to become contributing members of society and fully participate in civic activities, the UX discipline must ensure that technology is accessible to all. This goal is especially critical in the areas of e-health, e-government, and the economic benefits afforded by technology in the workplace.

37.8 User Experience Design

As noted earlier in this chapter, HCI has evolved from a rather narrow testing-focused human factors (HF) discipline to the much broader design approach of UX. New technologies, novel user interfaces, and the expanding number of relevant contexts require an increasing set of design solutions and research that informs them. Information technology developed many innovations, with some emerging

as "game changers" for the field. This section will examine some of these innovations and consider how they contributed to the emerging UX discipline. Innovations reviewed include

- Commercialization of the web
- Social networks
- Mobile computing
- Multimodal input
- Applications to apps
- Games

In the mid-1980s, computers were stand-alone machines used mainly for office-related tasks like text processing, creating simple graphics, and computing with spreadsheets (Gentner and Nielsen 1996). They were accompanied by a set of manuals often just as large and heavy as the computers themselves. Relatively few games were available and, since neither the necessary advanced network infrastructure nor the World Wide Web (WWW) was yet developed, almost nobody was connected to the Internet.

In such a context, where the focus was on individual users performing a task efficiently with minimal errors, HF methods were appropriate. These methods could be used to measure whether the necessary functionality was present and accessible to the user, and whether the tasks could be executed efficiently. Naturally, the focus was on the psychological and physiological characteristics of the user and the functionality and efficiency of the computer interface.

Interestingly, as simple as these interfaces may appear in the light of today's advanced ubiquitous computing devices, we cannot claim that the design of these so-called simple interfaces was ever mastered. A brief look at the interfaces in our daily surroundings will illustrate very quickly that the field still struggles to get even the simple interfaces right.

37.9 World Wide Web

The WWW, itself enabled by the existence of the Internet, was more of an enabler than a game changer. Websites started to sprout here and there, but the mostly academic users did not do much more than share documents. The interfaces with their static pages were rather a step backward, and this minimal interaction did not require HCI to do anything special (Myers 1998). This was all changed by the commercialization of the WWW and social networks.

37.9.1 Commercialization of the Web

As early as 1994, one "could even order pizza" on the web as Press (1994) somewhat incredulously stated. Online businesses slowly realized that websites had to appeal to customers in ways similar to brick-and-mortar stores. The shopping experience had to become appealing, or at least not upsetting. This included making sure that transactions were not only safe using secure web protocols, but that the customers trusted the businesses enough to hand over their credit card numbers. Furthermore, many of these online businesses had to deal with highly diverse customers that became increasingly global over time. Many sadly learned the bitter lesson that an attractive pitch to one group of customers may be offensive to another.

When is an interface like a website trustworthy (Hampton-Sosa and Koufaris 2005; Kim and Benbasat 2010)? This was an uncharted territory for HCI given its previous narrow focus on human–machine interactions. Furthermore, too often, trust and risk are predominantly addressed from a technology perspective (Camp 2000) even though that approach alone is problematic. Users need to decide whether they trust the people behind the technology. Websites had to reduce the appearance of risk, build long-term relationships, and build the reputation of the e-commerce business (Lanford and Hübscher 2004; Lynch 2010). These are issues not easily approached with traditional HF methods alone. Social interactions between individuals and businesses became very important.

The trustworthiness of a site cannot be easily tested in a lab setting because, for instance, people will spend their own money very differently than the experimenter's fake money.

37.9.2 Social Networks

The WWW also enabled online communities (Erickson 2011), typically focused on specific issues or goals, and social networks, which are much more focused on individuals (Howard 2010). Commercial sites tend to automate as much as possible and use as few as possible people on the business side of the interaction. Thus, whereas the interaction between people is often at the center of social networks, between a business and its customers, the interaction is a necessary but only secondary design focus. As a result, person-to-person interaction on business sites is often less than optimally designed, sometimes to such a degree that it discourages communication altogether.

In social networks, UX no longer focuses on individual users alone, but must now be designed for social interaction between individuals. Some individuals know each other, some do not. Privacy issues become important as it may not be clear to all users what information is accessible to whom. Real-world analogies are often severely flawed and may result in incorrect expectations, complicating these issues (Gentner and Nielsen 1996; Neale and Carroll 1997). For example, it is very easy to be linked—maybe indirectly—to people one is not aware of. These indirect connections often have no consequences in the real world, but this may not be the case in the virtual space. Do users realize this, given that the conceptual model of these linkages is often less than clear? Interestingly, some interfaces may even take advantage of these confusions. However, this could be considered unethical and not consistent with the goals of UX design.

With the incredible growth of online communities and networks into millions of users, the diversity of the users has also increased (Wade 2011). Differences across these users are no longer limited to interests and languages but also include different alphabets, social norms, and educational and literacy levels, to name just a few. As discussed earlier, accommodating such multidimensional diversity is a huge problem, considering that designing for a narrowly and well-defined audience tends to be difficult enough.

Because of such web-enabled interactions, UX needs to deal more with interactions between people including conceptual models of complex social interactions as they are defined by the various social networks. Privacy issues have also become increasingly more important given their legal implications.

37.10 Mobile Computing

Mobile computing was enabled during the mid-1990s by the availability of wireless networks and was initially mostly restricted to simple cell phones (Pierre 2001). Nevertheless, cell phones were soon commonplace all over the world including third-world countries. With the arrival of smart phones, their access to all the content on the WWW and many other services on the Internet through apps, the cell phone morphed into a general computing device enabling true ubiquitous computing. For many users, making phone calls has become a secondary function of these devices.

37.10.1 Integration in Daily Life

Over 87% of the world population had a mobile subscription for a cell phone in 2011 (Ekholm and Fabre 2011). The availability of smart phones is much lower at the moment at 17% of the population but growing quickly, and already two thirds of Americans between the ages of 24 and 35 own a smart phone (Nielsen 2012). Besides smart phones, many other interfaces use mobile computer technology and are neither considered computers including car dashboards, TVs, thermostats, and watches. Computational interfaces have become part of many people's daily life so transparently that it sometimes takes a power outage to realize they are now an inseparable component of our lives.

37.11 Multimodal Input

Frequently, new technologies like the WWW or mobile computing are the driving or enabling forces of new interfaces resulting in a challenge within the UX community to find appropriate ways to deal with them. Such technologies consist of hardware like ambient displays, augmented reality, haptic interfaces, and affective computing, as well as software like adaptive interfaces and recommender systems. Early implementations of new interfaces based on technological progress alone are typically rather awkward to use.

It is important that UX does not simply react to new technologies, hardware or software. From the very beginning of the innovation and design process, UX must be part of shaping how to use them and how to design optimum UXs enabled by new technologies (Sproll et al. 2010). User experience design, as the name implies, must be integrated early in the design process and not limited to testing before release. Thus, the UX community must be part of the development of new interfaces. The members of this community must help discover and adopt new interaction methods and technologies to improve the existing UX for a more diverse group of users who are demanding innovative interfaces, not just incremental improvements.

Computer input in the past was limited to keyboards and mice. However, this too is changing rapidly because they are too large and cumbersome to support ubiquitous computing. Many tablet computers and smart phones avoid the use of physical keyboards and rely heavily on gestures, voice input, and virtual keyboards. Most of these alternatives to physical keyboards and mice, like voice and gestures input, are often ambiguous and imprecise and therefore, cannot be taken literally. They need to be interpreted often based on the user's input history, his/her preferences, the physical location, time of day, and so on.

Users have also adapted to the new, somewhat limited interfaces. For instance, they have developed new languages because of message-length restrictions in SMS messaging on cell phones, microblogging, and online chat applications (Honeycutt and Herring 2009).

The old interaction paradigms need to be completely revised by shifting the tedious operations to the computer. Intelligent support can provide the necessary methods for multimodal user interfaces. Direct manipulation requires the user to implement the tasks using mouse and keyboard, but this is no longer necessary. For instance, take the remote control. We used to have to "program" them so that we could watch the show later, then this got reworded to "recording" a show, and finally, the universal remote managed to figure out for us which devices to turn on if we want to listen to a CD or watch a TV show. A goal-oriented approach lets us state our goal, and the system will take care of the rest (Faaborg and Lieberman 2006). For instance, telling the system that we want to watch the news will result in different choices, for instance, depending on the person asking for it and the time of day.

Intelligent approaches are necessary to support emerging interfaces. Intelligent agents interpret imprecise and ambiguous inputs; they reason about what actions need to be executed proactively; they execute certain tasks autonomously; and they can create individualized experiences by adapting the interface to the user. This approach is in contrast to the typical direct-manipulation approach, where the user has to tediously implement an action one simple step after another. Adaptive interfaces are already individualizing experiences in educational applications including museum exhibition guides and in many recommender systems used in e-commerce sites (Aroyo 2011; Brusilovsky 2012; Brusilovsky et al. 2010).

However, many of these intelligent user interfaces require a user model consisting not only of information explicitly provided by the user but also behavior data collected by the interface. Related to the earlier discussion of unintended consequences, this raises serious privacy issues that need to be taken into consideration during the design process; they cannot be treated simply as an afterthought.

New technologies open up completely new ways to interact with computational devices as well as with the real world via computational devices. Considering how tricky it can be to develop a "normal" user interface, it is not surprising that applications of new interface technologies are often initially suboptimal. This should not keep us from using them. However, it is critical that the UX community actively participates in helping to shape the use of new technologies in ways consistent with the abilities and goals of people.

The UX with many of these new technologies can be aptly described as reality-based interaction (Jacob et al. 2008). The goal is to go beyond the stale WIMP (window, icon, menu, and pointing device) interfaces. Ubiquitous computing implies that we can access the Internet from anywhere at any time, which we often do with laptops or smart phones. However, any computational device can take advantage of this anywhere/anytime access of information. With tangible interaction (Hornecker 2009; Shaer and Hornecker 2010), information is not just displayed on a screen but can be integrated into the real-world interaction. Leveraging the infinite variety found in nature for displaying and interacting with information is important, that is, the designers need to consider existing natural and artificial objects instead of adding yet another rectangular screen. Why is a classroom wall just a wall to hold paint and separate groups of learners? Why is everything in stores, museums, and office buildings labeled with static paper labels? To find innovative answers to such questions, UX designers need to consider the whole body of a person and also physical spaces, thus moving into the realm of architecture (Alexander et al. 1977). The arts also need to be included when designing large public displays and, especially, ambient displays. Ambient displays show information in a nonintrusive way, allowing the user to perceive it preattentively with little cognitive load (Mankoff et al. 2003). This is quite different from the usual design elements in more traditional user interfaces, and therefore, we cannot simply apply the same design and evaluation heuristics (Mankoff et al. 2003; Pousman and Stasko 2006). Ambient displays are sometimes used to change the behavior of the user (Jafarinaimi et al. 2005), something that is often explicitly avoided in more traditional systems where the business process is to be supported, not disrupted.

For a long time, user interfaces have been rather restrictive: it is easy for the device to interpret a key press or a mouse click; however, it is not trivial for a user to translate some complex goal into a lengthy sequence of digital actions. As the computer becomes more and more invisible (Norman 1998), multimodal interaction will become more important, enabling design to become really user-centered for all users, no matter what their specific needs are, and in all social and physical contexts.

37.12 From Applications to Apps

With mobile computing, the traditional focus on large software applications with ever-expanding functionality has shifted to much smaller, highly focused apps. This move has a major impact on the design, development, and marketing of software.

Apps typically focus on a narrow, well-defined set of functions normally targeting an audience with similar goals. As a consequence, the interface can target the audience better, and the conceptual model of an app can be more coherent. The functionality needs to be restricted and highly focused on the tasks targeted by the specific app (Wroblewski 2011). As a result, the relative simplicity of apps, as compared to the highly complex applications used on desktop and laptop computers, allows small teams, even individuals, to design, develop, and market a software product, potentially to a worldwide market.

Due to the narrow focus of apps, users need only buy the functionality they are interested in, which is then reflected in a lower and more appropriate pricing model than when paying for lots of functionality that is of no interest to the user (Muh et al. 2011). For instance, some text processors on the desktop contain every functionality imaginable, plus the kitchen sink. On a tablet or smart phone, this functionality is separated out into specific apps providing a dictionary, an outliner, or a bibliography database, to name a few. The new pricing model, where the user pays proportionately to use, is terribly disruptive to traditional design and pricing models. However, to sell an app, the interface needs to market itself within minutes or even seconds to the potential buyers, as they frequently make a purchase decision not based on a long evaluation but based on word-of-mouth and a quick-and-dirty evaluation at purchase time. Thus, it is important for apps to be easy-to-use with a very flat learning curve supported transparently within the application. Learning is seamlessly embedded, similar to games, and the interaction is using gestures more or less based on physical interactions in the real world. However, such natural user interfaces are not necessarily the panacea for all mobile interactions, at least not in its current state (Norman and Nielsen 2010). Most gestures have to be learned and differ from culture to culture.

37.13 Games

Although computer games are as old as computers themselves, they have interesting characteristics not found, unfortunately, in many other computational user interfaces. Computer games used to be text-based but soon evolved into complex, sometimes massively multiuser, games with highly interactive, graphical user interfaces. Today, games are everywhere, part of social networks, mobile platforms, but also in the physical world where the boundaries between physical and computation world start to blur.

A wide range of games are played on smart phones by people all over the world with many different sociocultural backgrounds. Yet, most of these users do not seem to have serious problems learning to play these games, even though the interfaces are frequently rather complex. Although the learning curves may be just as steep as in other complex software, there seems to be a much better support of the user to overcome this obstacle. The immersive character of games often results in users trying harder at mastering the software application than when having to solve an unauthentic, imposed problem (Rooney 2007). Furthermore, in games, users are typically scaffolded (Puntambekar and Hübscher 2005) with context-sensitive support built-in and not separate from using the software to accomplish a task (Wroblewski 2011).

When analyzing tasks supported by an interface, it is important to also understand the users' goals and why they want to complete that task. While the goals for playing games are often intrinsic, the ones for doing many work-related tasks are not. They are imposed from the outside, and as a result, it may not be surprising that gamers may be more willing to spend some effort to learn a nontrivial user interface. Furthermore, the social interaction between the users is often characteristic in helping newcomers to get more proficient at playing. These observations should not be used as an excuse for missing support for novice users of a product, but as a suggestion of where to look for improved ways of helping the user to master an interface.

Although most UX designers do not design games, we should attempt to appropriately apply lessons learned within the game-design community to a broader class of interfaces. The mechanics-of-games guidelines (Sicart 2008) that drive an enjoyable game-playing experience can be adapted to the design of nongame user interaction (Zichermann and Cunningham 2011). Unlike most software that requires training or frequent trips to online documentation, games rarely require users to go through a tutorial. Support is seamlessly integrated as part of the game-playing activities. Such scaffolding needs to be added to all nontrivial interfaces, not just educational ones. Furthermore, many educational applications are not very interactive, and students rarely become as immersed in them as in games.

37.14 UX Theory and Practice: Looking Forward

The pace of new technological developments and their integration in the lives of an increasingly diverse user community will continue to accelerate. User experience research and design must continue to evolve accordingly. Again, the need to change should not be viewed as a failure of past practice, but rather seen favorably as a discipline's response to the ever-shifting demands of new technologies, enhanced interaction possibilities, and expanded user communities. This future produces challenges for the discipline and profession on a number of different levels as considered in this chapter:

- Address the needs of new technologies, user populations, and an expanded array of human behaviors in academic programs in HCI, human factors, and UX design.
- Expand the research agenda to address issues surrounding a more diverse user population and newly encountered behaviors. Most especially, this expansion should include the seamless integration of a more global research base and the fundamental tenets of universal design.
- Appreciate the intersection of UX with the larger business enterprise including, but not limited to marketing and competitive advantage in increasingly competitive markets.

- Understand more deeply how this strategic role shapes the research agenda moving forward and informs the practice.
- Expand the guiding research for new modes of interaction and their possible effects, both positive and negative, in the UX. From a purely interaction design perspective, the interaction experience has finally realized its full multimodal potential involving virtually all of the human senses. In practice, the UX profession must develop a systematic approach to optimizing the multimodal interaction experience, delivering highest possible value with minimal negative consequences.
- Consider the profession's ethical role and responsibilities related to the consequences of the technologies they design. There is no easy or clear answer here; the important thing is that the profession continues to consider these issues and not blindly focus on the intended outcomes.

This agenda should not be viewed as negative or threatening to the past focus of the HCI discipline. Instead, this expanded view has provided exciting new research opportunities and increased recognition of the value the discipline offers the user as well as the product design organization.

In practice, a successful product or service must encompass each of the elements discussed in this chapter. User experience professionals must understand the relevance of market conditions, appreciate how those conditions shift over time, and appropriately coordinate a response. They must recognize and leverage the implications of game-changing technologies, appreciate the expanding array of cognitive and perceptual factors associated with those technologies, weigh these elements appropriately based on an actual user population, use context and value realized. And finally, the UX professional must balance the human element against business, regulatory, marketing, and technical requirements. Figure 37.3 frames a process that considers each of these elements.

Beginning with a deep knowledge of human behavior and ability traditionally captured in HCI, the UX professional complements this knowledge with research gathered through user research identifying appropriate contextual factors. From this effort, they glean insights that lead to design innovation and implementation. Finally, they anticipate and accommodate the changing demands of the marketplace through a deliberate and systematic focus on sustaining innovation.

In this model, UX is seen as an art, science, and business. Through this model, the discipline will define their research agenda and professional practice moving forward. By deeply integrating and managing this process, they can avoid the narrow focus of the past. Instead, the discipline will greatly increase the probability of a carefully orchestrated UX, ultimately delivering value to both user and business.

Using Information Systems and Technology to Support Individual and Group Tasks

38

Individual-Level Technology Adoption Research: An Assessment of the Strengths, Weaknesses, Threats, and Opportunities for Further Research Contributions

Viswanath Venkatesh
University of Arkansas

Michael G. Morris
University of Virginia

Fred D. Davis
University of Arkansas

38.1 Introduction

Imagine the following conversation between two researchers at a research university located anywhere in the world:

Doctoral student/new researcher: "I've been reading about how and why people choose to use new technologies and am very interested in building on some of the recent technology adoption models."

Doctoral advisor/senior researcher: "I don't recommend it. There has been so much work done in that area that it is virtually impossible to demonstrate a contribution and get a paper on technology acceptance accepted at any top journal anymore. You would be much better off spending your time working on… ."

Although the aforementioned dialog is imagined, the issue at the core of the conversation is not. How does a researcher interested in the broad phenomenon of individual-level technology adoption make a significant contribution? There can be little doubt that technology adoption has been one of the most dominant, if not *the* most dominant, streams of research in information systems research

(Benbasat and Barki 2007; Venkatesh et al. 2007), and papers from this stream of research are among the most cited in all of business and economics (ScienceWatch.com 2009). A quick examination of the titles and author-supplied keywords indicates that at least 7 of the 10 most highly cited papers in *MIS Quarterly* (*MISQ*) and 11 of the top 20 are related to individual "user acceptance" of information technologies (http://www.misq.org/skin/frontend/default/misq/pdf/MISQStats/MostCitedArticles.pdf). Moreover, the technology acceptance model (TAM), with Venkatesh et al. (2003) as the most influential paper in this stream, has been identified as one of the four fastest growing research fronts in business and economics (Sciencewatch.com 2009). Reflecting on our work in this stream, some of the most-cited papers in various journals are related to technology adoption: the two papers that originally introduced TAM—i.e., Davis (1989) and Davis et al. (1989)—are the most-cited papers in *MIS Quarterly* and *Management Science*, respectively; the paper that introduced unified theory of acceptance and use of technology (UTAUT)—i.e., Venkatesh et al. (2003)—is the second most-cited paper in *MIS Quarterly;* the paper that introduced TAM 2—i.e., Venkatesh and Davis (2000)—is the fifth most-cited paper in *Management Science;* papers that studied the antecedents of TAM constructs—i.e., Venkatesh and Davis (1996) and Venkatesh (2000)—are among the most-cited papers published in *Decision Sciences* (most cited) and *Information Systems Research* (second most cited), respectively. Thus, it seems clear that technology adoption is and is likely to remain an area of importance and interest to business researchers. If so, identifying answers to the question of how to identify and make a significant theoretical contribution to this very rich research stream is of vital importance to the academic community.

The maturity of individual-level technology adoption research has fueled much debate about whether this area of research is so mature that there are no more interesting and unanswered questions related to technology adoption left to be answered—this, in fact, is the central issue tackled in this chapter. This debate has revolved primarily around TAM (Davis et al. 1989). A special issue of the *Journal of AIS* in 2007 was dedicated to the discussion about TAM and related models (hereafter referred to as *JAIS-TAM*). The articles in the *JAIS-TAM* largely reflected the *subjective* reactions of several senior scholars to questions ranging from whether there is a future in TAM research to whether the model has even been good for the field at all. Criticisms of TAM range from its simplicity, to research simply replicating TAM in new contexts or making minor refinements to the model, to TAM hindering the development of more complex theories and detracting from the study of more relevant problems (see Bagozzi 2007; Benbasat and Barki 2007; see also Lee et al. 2003). In light of prior research explaining up to 70% of the variance in intention to use a system (Venkatesh et al. 2003), articles in the *JAIS-TAM* ranged from strongly hinting to explicitly stating that individual-level technology adoption research as we currently know it has almost no future.

Nonetheless, from a practical perspective, there is little doubt that technology adoption continues to be a significant business challenge as information system projects continue to fail at an alarmingly high rate (see Davis and Venkatesh 2004; Devadoss and Pan 2007; Morris and Venkatesh 2010). Despite apparent progress on the scientific front, if project success rates in practice have not improved, there are two possible explanations: (1) practice is disconnected from science—i.e., the message has not reached the practitioners or they have not applied the "lessons learned" from scientific research and/or (2) science is disconnected from practice—i.e., researchers have failed to provide meaningful actionable guidance (see Benbasat and Zmud 1999, 2003; Sambamurthy 2005; Straub and Ang 2008; Weber 2003). Our belief is that technology adoption research remains vital and is one important vehicle for addressing both of these broad gaps.

One of the sentiments conveyed in the *JAIS-TAM* is that although TAM and the associated body of research have been useful and served to integrate disparate bodies of research in the 1980s, it may have well outlived its useful life (Benbasat and Barki 2007). Benbasat and Barki (2007) further note that TAM is, at best, a middle range theory and, to advance scientific inquiry, it is important to move beyond TAM. Most of the other articles in the *JAIS-TAM* concurred with this basic idea and suggested that now, about 20 years after the publication of the original TAM papers, was an appropriate time to further our thinking about technology adoption research. We concur that significant progress has been made

(see Venkatesh et al. 2007 for a review) and that more replications and minor extensions are not likely to be helpful in moving the boundaries of the domain forward. By definition, such approaches will only advance our knowledge in a very limited way. Thus, we agree with many scholars who have suggested (in the *JAIS-TAM* and elsewhere) that technology adoption research is stagnant in many ways, consistent with the normal science phase of a stream of research (Kuhn 1996; see also Silva 2007). In suggesting potential future research directions, the collection of papers in the *JAIS-TAM* presented some broad ideas about how one might make a theoretical contribution in this stream. Of course, each of the papers brought its own ideas (and biases) to the debate, and there was no attempt to group or coordinate the suggestions. The potential directions can be grouped into the following general categories:

1. *Determinants*: Benbasat and Barki (2007) point to the need to focus on determinants specifically tied to the IT artifact (i.e., system design characteristics). Similarly, Venkatesh et al. (2007) issued a call for additional determinants based on the fact that work in the reference disciplines has examined a broader set of determinants. Most of the work in this stream to date has primarily studied only technology characteristics and technology-related individual characteristics as determinants.
2. *Consequences/outcomes*: The various papers in the *JAIS-TAM* similarly called for richer theorizing around the outcomes and consequences of technology adoption and use (see Lucas et al. 2007; Venkatesh et al. 2007). Researchers have begun to probe this area more deeply (Barki et al. 2007; Burton-Jones and Straub 2006; Venkatesh et al. 2008); however, work in this area remains in its infancy.
3. *Alternative theoretical mechanisms*: Many have called for richer theorizing by examining alternative mechanisms that can better explain technology use. Bagozzi (2007) proposes a different theoretical perspective on technology adoption, grounded in much of his previous work. Citing Kuhn's thoughts on scientific revolution, Benbasat and Barki (2007) have called for pushing the boundaries of our thinking with regard to theoretical explanations. They cite Wixom and Todd (2005) as an exemplar of such work. Lucas et al. (2007) call for research on multilevel models that can lead to a richer understanding of the phenomenon, and Schwarz and Chin (2007) call for a rethinking of the very meaning of acceptance—habit is used as an example of an alternative theoretical explanation (see Kim 2009; Kim et al. 2005; Polites and Karahanna 2012; Venkatesh et al. 2012). Venkatesh et al. (2007) note the scientific progress made in related reference discipline in examining alternative theoretical mechanisms and draw parallels to the work on technology adoption.
4. *Analytical issues*: Straub and Burton-Jones (2007) are most forceful in raising concerns related to common method bias, and others have recently echoed similar concerns about the research in this area (Sharma et al. 2009). Another example of a potential advance by leveraging more recent analytical techniques is presented by Lucas et al. (2007), who suggested the use of hierarchical linear modeling as a mechanism for providing new theorizing and analysis across levels that have largely been ignored in the work to date. Similarly, Kang et al. (2012) suggested multilevel analyses for the adoption of collaborative technologies as a fruitful step for additional work.

38.2 Strengths, Weaknesses, and Threats of Current Technology Adoption Research

As noted, although many authors have offered important and valid critiques of technology adoption research, it is first worth noting that the prior research has a number of important strengths. First and foremost, prior work has provided a mechanism for integrating disparate bodies of research. With its roots in social psychology, particularly the theory of reasoned action (TRA; Fishbein and Ajzen 1975) and the theory of planned behavior (TPB; Ajzen 1991), models of technology adoption tested in workplace settings have been used to explore individual use of technologies, ranging from personal productivity

tools used in organizations (Davis et al. 1989) to electronic commerce applications (Duan et al. 2009), and everything in between. Clearly, the generality of the various technology adoption models has helped create a strong, cumulative tradition, with a rich set of empirical results. For example, a meta-analysis examining the role of voluntariness included a sample of 71 studies on technology acceptance (Wu and Lederer 2009). As indicated earlier, studies on technology adoption are among the most highly cited in all of business and economics and, thus, continue to exert a strong influence on research in various fields within business and economics.

Unfortunately, many of these strengths, when turned around, contribute to the stream's most visible weaknesses. For example, although the extant literature provides a number of influential models of adoption capable of helping scholars understand a vast array of technologies, their generality precludes including any direct design guidance (Venkatesh et al. 2003). This criticism has been recurrent within this stream of research itself for quite some time (Benbasat and Barki 2007; Venkatesh and Davis 1996). Further, although the models are easy to apply, they are heavily reliant on perceptions as predictors of use rather than performance itself (Nielsen and Levy 1994; Venkatesh et al. 2003). Likewise, most technology adoption research starts and ends with the question on what drives technology use itself. This is an important and appropriate starting point for understanding the implementation of information systems in organizations. However, use (in and of itself) offers few advantages to organizations or managers; rather, the consequences of use are factors that are most relevant to researchers and managers interested in improving productivity and performance (see Burton-Jones and Straub 2006; Morris and Venkatesh 2010).

The series of identifiable strengths and weaknesses gives rise to a series of potential threats or concerns with the current state of technology adoption research. Kuhn (1996) argues that scientific thought in any given area proceeds from "prescience" (that lacks a central unifying paradigm), followed by "normal science" that is typified by a program of research on a phenomenon that is guided by foundational work acknowledged by the community as the basis for further investigation and practice. Kuhn (1996) charts the progress of dozens of scientific domains that follow a similar pattern of evolution. One of the main threats associated with this period of "normal science" is that it crowds out or suppresses inquiry that might lead to more revolutionary developments or a "paradigm shift." Given the volume and impact of TAM and related follow-on models (e.g., TAM2, UTAUT, TAM3, UTAUT2), one can argue that by Kuhn's criteria, the existing research on technology adoption provides an almost textbook example of a dominant theoretical paradigm that is in a period of "normal science" (see Silva 2007; Straub 2009a).

As opposed to a series of "one off" recommendations, one of our goals in providing a more organized, comprehensive framework in this chapter is to help structure future research in order to break out of the dominant theoretical paradigm and open new avenues of thought. In so doing, many researchers interested in this area of study might help create one or more revolutionary theoretical perspectives that lead to advances that might otherwise have been missed or ignored. A similar line of reasoning holds for the primary methodological techniques used in much prior work in this domain. Just as one can argue that there is a dominant theoretical paradigm in this stream, based on the methods, measures, and analytical techniques used in the vast majority of the influential papers in the stream, one can argue that there is a dominant methodological paradigm as well that results in a biased set of conclusions (Sharma et al. 2009; Straub and Burton-Jones 2007; Straub et al. 1995). Like a dominant theoretical paradigm, a dominant methodological paradigm can also have a stifling effect on creativity and scientific innovation.

We thus acknowledge and agree with many of our colleagues that demonstrating a meaningful contribution within the technology adoption and research stream can be a daunting task. The central question of this chapter is to determine what to do about it. On the one hand, the community can adopt a skeptical stance (as the fictional senior researcher in the opening paragraph) and back away from the challenge, essentially saying that the field has "been there, done that," and it is time to move on to other important areas of research. Or, on the other hand, the community can look for ways to break free from the shackles of the existing dominant theoretical paradigm by supporting creative research that builds upon the legacy of work in what still appears to be an ongoing phenomenon

TABLE 38.1 Strengths, Weaknesses, Opportunities, and Threats for Current Technology Adoption Research

Strengths	• Remains a highly influential body of work within the IS discipline • Investigates a problem important to researchers and managers • Integrates disparate bodies of research • Applies to many different technology contexts • Provides a well-understood model • Explains a high percentage of variance in intentions and use • Is easily applied and modified
Weaknesses	• Does not offer direct design guidance for improving system acceptability • Emphasizes the importance of perceptions over actual behavior • Focuses on use as the primary dependent variable of interest
Threats	• Creating and reinforcing a dominant theoretical paradigm • Creating and reinforcing a dominant methodological paradigm • Propagating the perception that there is nothing new to be learned • Stifling scientific creativity and innovation • Finding ways to demonstrate a significant contribution • Becoming stuck in the normal science phase
Opportunities	• See framework (Figure 38.1)

of interest. Table 38.1 briefly summarizes the strengths, weaknesses, opportunities, and threats that we have outlined in the preceding analysis. In the sections that follow, we outline what we (and others) believe constitutes a theoretical contribution and offer our ideas for how to craft work that can make a strong contribution to this research stream.

38.3 Making a Contribution: Promising Future Research Directions

Before presenting a framework outlining future research directions, we first highlight some of the critical elements deemed essential for making a theoretical contribution drawn from the comments of Benbasat and Zmud (1999), Sutton and Staw (1995), Weber (2003), and Whetten (1989), among others. Many of the points made by these scholars have been reinforced in the editorial statements of the editors at *MIS Quarterly* (Saunders 2005; Straub 2009a; Weber 2003) and *Information Systems Research* (Sambamurthy 2005).

Weber (2003), in his editorial comments, stated that theory "is an *account* that is intended to explain or predict *phenomena* that we perceive in the world" (p. iv, emphasis in original). His articulation of the various ways in which theoretical contributions can be made is consistent with those described in Whetten's (1989) influential remarks. Whetten (1989) noted and discussed four building blocks of theory development: *What* (constructs), *How* (relationships), *Why* (justification), and *Who, Where, When* (conditions). *Why* is likely the "…most fruitful, but also most difficult avenue for theory development" (Whetten 1989, p. 493). Weber's (2003) commentary echoes this point by suggesting that theory should be able to account for phenomena. Also, he notes that the constructs and relationships serve as bases for building richer explanations for phenomena of interest. *Who, Where,* and *When* also possess potential if the conditions being examined are qualitatively different from prior research and/or if the nature of the relationships and outcomes are substantially different from prior research that helps understand the limits and boundaries of existing knowledge, thus furthering our understanding of the phenomenon at hand. As theorists have often noted, good theory is usually laced with a set of convincing and logically interconnected arguments. It can have implications that we might not be able to see with our

naked (or theoretically unassisted) eye. It may have implications that run counter to our commonsense. As Weick (1995) put it succinctly, "a good theory explains, predicts, and delights" (p. 378).

In Straub (2009a), the four required elements for a paper to be accepted at *MIS Quarterly* or other premier journals were identified to be (1) blue ocean ideas,* (2) research questions that are nontrivial, (3) popular themes, and (4) the use and development of theory. Both the notion of blue ocean and the importance of research questions ultimately boil down to contribution (Straub 2009a). As he goes on to note, "I believe that it is the unbeatable combination of a reasonably well applied theory answering interesting, novel questions in a well-known thematic stream of work that leads to blue oceans" (p. vii). In his example of nontrivial research questions, he notes that one of his papers (Gefen and Straub 1997) had a "simple enough" research question about how gender affected the causal relationships in TAM but given that the research question had not been studied before, the review team felt that the question was nontrivial. We leverage Straub's (2009b) articulation of "blue ocean ideas" to propose our framework. Researchers can use the framework as a starting point to break out of the normal science phase that seems to currently typify technology adoption research (Kuhn 1996; Silva 2007; Straub 2009a).

The previously mentioned suggestions and guidelines for a theoretical contribution suggest four elements that are important motivators for future technology adoption research. After making a few observations about the relevance of each element for future technology adoption research, we then present a more comprehensive framework that can be used to motivate research that we believe has the potential to make a substantive contribution to the stream.

1. *Answer unanswered research questions related to important and interesting phenomena*: The pursuit of unanswered research questions should be considered by keeping in mind the need to focus on important and relevant business management phenomena (see Benbasat and Zmud 1999). Triviality of phenomena or findings is a fatal flaw for which papers should be rejected (see Saunders 2005; Zmud 1996). In other words, simply because a question has not been previously studied does not make it worthy of study. For example, even though it may not have been studied yet, research applying existing adoption models to the adoption of the next Windows operating system does not make it important or interesting. To this end, we concur with some of the ideas expressed by Benbasat and Barki (2007) by suggesting that one useful area within the technology adoption stream that has the potential to specifically address unanswered research questions—even within the context of existing models—is the exploration of determinants related to the IT artifact and theories that directly tap into properties of specific classes of technologies.
2. *Question/challenge prior theoretical perspectives and consider new theoretical perspectives*: Technology adoption research is dominated by research from the same paradigm of research (i.e., social psychology) from within which TAM was originally developed. We believe that questioning and challenging this dominant theoretical paradigm is essential to developing new theory and going beyond the boundaries of what is firmly established (see Sambamurthy 2005; Saunders 2005; Weber 2003; Zmud 1996). Thus, technology adoption research must leverage alternative theoretical perspectives to enrich our understanding, make progress, and provide innovative solutions to technology implementation and diffusion challenges. This can be achieved either by employing entirely new theories or by integrating previously unused theories in this context. Within technology adoption, examples of employing truly *new theories* include those offered by Kim and Kankanhalli (2009) using a *status quo* perspective and Malhotra et al. (2008) using organismic integration theory; unfortunately, although such examples exist, they are all too rare. Perhaps not surprisingly, there are a few more examples of integrating *previously unused theories* into the technology adoption context, including those by Sykes et al. (2009) for social networking, Devaraj et al. (2008) for personality, and Wixom and Todd (2005) for technology adoption and satisfaction.

* Drawing from marketing, Straub (2009b) describes blue ocean ideas to be those that are extremely innovative ideas that make competition irrelevant.

3. *Relative to prior research, develop richer and more comprehensive explanations*: A natural by-product of questioning and challenging prior theory is that the process of thinking through such new theoretical perspectives and executing research that builds on new theory will almost certainly lead to richer and more comprehensive explanations of underlying phenomena (see Sambamurthy 2005). Although most new theoretical perspectives, as discussed earlier, can provide some insights into technology adoption processes, we believe there will be particular benefit and richness from spanning across levels of analysis. We must emphasize that we are *not* suggesting that technology adoption research should simply apply theories from other disciplines; rather, it should use/develop theories in ways that can help explain the unique elements of technology diffusion that will likely call for new constructs, relationships, explanations, and/or boundary conditions (see Herold et al. 2007; Johns 2006). Alvesson and Karreman (2007) note that examining general theories in specific contexts is essential to identify a theory's boundary conditions in order to create the opportunity to extend existing theories. Identifying relevant boundary conditions and contingencies has been far too underrated in technology adoption research (see Weber 2003). We believe that a compelling demonstration of how relationships may change under new conditions—for example, gender as a moderator of key relationships (Venkatesh and Morris 2000; Venkatesh et al. 2000) or the implicit moderation of relationships when different types of systems were investigated (Van der Heidjen 2004)—can represent an important contribution if they are anchored strongly in theory.
4. *Expand the nomological network of relationships*: In most prior research on technology adoption, the nomological network of relationships starts with technology perceptions (on the predictor side), and with few exceptions extends only as far as technology use (on the outcomes side). Building on the ideas of Sutton and Staw (1995), we suggest the need to study broader organizational and/or social phenomena where technology plays a role. We call for research to fully explicate and understand the determinants of technology-related constructs and behaviors and appreciate the impact of technology on outcomes that go beyond use as the primary dependent variable of interest. For example, it is surprising that little or no research on job satisfaction in organizational behavior or psychology has considered technology in any significant way despite the fact that technology has, without question, had a pervasive role in organizational life for well over two decades. A similar problem exists when examining research on technology acceptance and use at the individual level—researchers have simply not ventured far beyond technocentric constructs. Recent examples that guide us in this direction include Morris and Venkatesh (2010) who study job satisfaction and Raghunathan et al. (2008) who study stress. These exemplars illustrate why it behooves us to extend the reach and scope of our nomological networks (see Sambamurthy 2005) by bringing fresh new perspectives to the individual technology adoption phenomenon.

Against the backdrop of these four suggestions, we present a framework that we believe can help guide researchers interested in technology adoption topics (broadly construed) make a substantive contribution to the stream. For example, starting with a generic model of acceptance as the core layer in our framework, we have presented ideas for how researchers might begin to address unanswered questions and probe boundary conditions (points 1 and 4). From this starting point, we have constructed what we call "layers" that provide some specific suggestions and—more importantly—offer researchers a structure for finding ways to contribute meaningfully to the technology adoption literature. Working out from the core layer, our framework includes technology, individual, organizational, societal, and methodological/analytical layers. We believe that, as researchers explore ideas within and across the layers in the framework, it may help illuminate ideas that can be used to exploit potential new theoretical perspectives (point 2) and expand the nomological network of relationships (point 3) to new areas that have not been previously addressed or that are just starting to emerge in the literature.

Within the framework, we offer a number of specific suggestions that we believe have a high potential for making a contribution. This list is not exhaustive, but instead, it is meant to be illustrative of how

the framework might be applied. Implicit in the framework and building on the suggestions of other researchers is the notion that research agendas must be theory-driven. Simply because a construct or an idea appears in the framework does not, in and of itself, mean to imply that we believe all research on that focal construct or idea constitutes a contribution by definition. Rather, it means that we believe that research that focuses on that particular element or dimension of the framework has the *potential* to offer a contribution. In other words, it is incumbent upon researchers interested in studying the phenomenon to motivate their work based on the theory within the relevant dimension of the framework, not simply use the framework as the sole motivator for their work.

The first of the elements of the framework include technology adoption determinants (e.g., technology characteristics, individual characteristics, and job characteristics); technology adoption outcomes (e.g., job satisfaction, job performance); intra-individual alternative theoretical mechanisms (e.g., non-productive use or continuance); and extra-individual alternative theoretical mechanisms (e.g., teams, social networks, culture). In addition to theoretically driven research directions, the framework presents research directions that involve novel analytical techniques, such as polynomial modeling and agent-based modeling (ABM). Research that leverages new analytical techniques can span the theoretical ideas presented earlier and may, in fact, reveal new constructs or phenomena that were previously unaccounted. We hope that this framework can help scholars pursue important questions and, perhaps equally important, help reviewers and editors make fewer "type II" errors (see Straub 2008) when evaluating work in this stream.

Figure 38.1 and Table 38.2 present our framework and summarize our future research directions. We elaborate on this next.

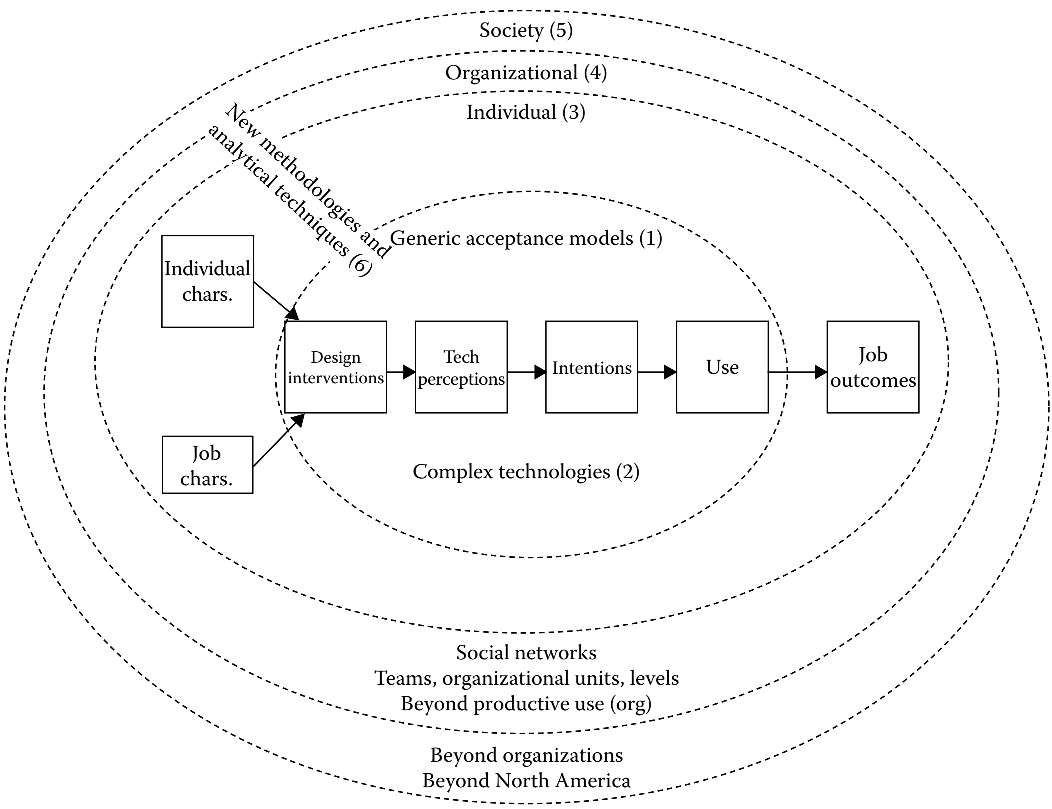

FIGURE 38.1 Framework for technology adoption research contributions.

TABLE 38.2 Potential New Research Directions

Framework Layer	Concept	Illustrative Focal Directions
1. Existing models	Interventions	• Actionable design characteristics • Training mechanisms
	Reconceptualizing constructs	• Nonproductive use • Deep structure use • Various technology adoption constructs
2. Technological	New or complex technologies	• Enterprise systems • Workflow management • Decision aids/agents
3. Individual	Individual characteristics	• Personality • Other theoretically driven demographic or psychographic constructs
	Job characteristics	• Task significance, skill variety, task identity, autonomy, feedback • Job demand, job control
	Job outcomes	• Job satisfaction • Organizational commitment • Turnover intention • Job performance
4. Organizational	Social networks and teams	• Size, shape, centrality, density • Team variables (e.g., cohesion)
	Organizational units or levels	• Multilevel analysis of technology use • Nonproductive use (team or org-level)
5. Societal	Beyond organizations	• Environment • Public policy • Culture
	Beyond North America	• Culture • Societal norms • Questions of generalizability • Questions of omitted variables
6. Methodological and analytical	New methodologies and analytical techniques	• Curvilinear effects • Polynomial modeling • Common method bias • Multilevel analysis (see organizational layer) • Simulation • Network analysis (see organizational layer)

Note: These are illustrative areas that we see as important, but, of course, do not represent an exhaustive list of possible directions that could constitute a contribution.

38.3.1 Existing Models' Layers

38.3.1.1 Interventions

In order for research on technology adoption to have meaningful and maximal implications for system designers and managers, it is essential to design and test interventions that can be used in practice. Thus, looking at specific technology characteristics is a particularly promising avenue for future work. The interventions that can be studied range from specific design characteristics (Cyr et al. 2009; Lee et al. 2012; Lohse and Spiller 1999; Sun 2012) to training (Venkatesh 1999) to other types of managerial interventions (see Leonard-Barton and Deschamps 1988). The pervasive interest in the technology

artifact (see Benbasat and Weber 1996; Benbasat and Zmud 2003; King and Lyytinen 2004; Orlikowski and Iacono 2001) certainly suggests that the design, development, theorizing, and evaluation of interventions, particularly tied to specific system design characteristics, are important. With respect to technology adoption in particular, Benbasat and Barki (2007) state that "…theorizing the effect of system characteristics on TAM variables is definitely harder" but go on to advocate this type of work as a valuable contribution to the discipline. In addition, the integration of technology adoption research with human–computer interaction research on usability is a noteworthy step in the direction of tying design interventions to known determinants of adoption (Agarwal and Venkatesh 2002; Palmer 2002; Zhang et al. 2002). It is important to note that we are not advocating a cycle of never-ending elaboration, incremental testing, and documentation of a range of outcomes associated with the use of various design characteristics, such as those specified by "design gurus" or best practices. Rather, we are calling for theory-driven examinations of design options or other interventions, grounded in research in software engineering, human–computer interaction, information visualization, and IS (among others). Such an exploration of key design interventions offers the potential for answering interesting questions, extending the nomological net of relationships, and providing a richer explanation for the adoption of new systems in ways that are practically relevant and keep the core properties of technologies as the appropriate focal point of study (Benbasat and Zmud 1999, 2003).

38.3.1.2 Reconceptualizing Constructs

For obvious reasons, technology adoption research has had a near-solitary focus on what could be termed "productive use." Inherent in this work is one critical assumption: more use is better. This assumption implies that benefits derived from technologies will be maximized when the use of technologies is also maximized (Agarwal 2000; Devaraj and Kohli 2003; Venkatesh and Davis 2000). The broader implication of this assumption is that maximizing use always leads to more positive outcomes (in a linear fashion) and that there are no significant negative consequences associated with such use. In contrast, the trade press in the past decade or so has been rich with stories of several negative consequences of technology use, such as excessive Internet use, often leading to dysfunctional outcomes including decreased social involvement and increased depression (Kraut et al. 1998a; Young 2004). Although technology adoption research has long advocated use as a positive outcome that drives other positive outcomes, such as increased productivity at work and improved home life, psychologists have begun to focus on the potential negative consequences of excessive technology use. In addition to negative impact that technology can have on users in homes, technology use can result in loss of productivity due to employees using technologies to engage in nonwork-related tasks—e.g., chatting, browsing, and playing games—without being noticed. Interesting streams of research from psychology, sociology, and organizational behavior on addictions and withdrawal behaviors can be leveraged to help further our understanding of wasteful technology use, its determinants, its consequences, potential contingencies, and helpful interventions (see Tarafdar et al. 2010; Turel et al. 2011). However, this first calls for a fundamental rethinking of the use construct in order to broaden the scope of technology adoption research, paralleling the way the reach of technologies themselves has broadened.*

Burton-Jones and Straub (2006) challenged the traditional conceptualization of system use in favor of richer conceptualizations. Specifically, they proposed cognitive absorption and deep structure use as viable alternative dependent variables. They provided preliminary evidence that these conceptualizations of use were more strongly related to task performance. Burton-Jones and Gallivan (2007) and Barki et al. (2007) have also made suggestions about how to move forward with better conceptualizations of this key construct. Yet, much work remains to be done. What are the predictors of these conceptualizations of use? What are its consequences? How well do existing models of technology adoption

* Although beyond the immediate focus of this discussion, other areas that could be of interest along these lines include rethinking the conceptual foundations and role in the nomological network for various other constructs, such as service quality (see Wixom and Todd 2005).

predict these conceptualizations? What are the temporal dynamics and other contingencies involved in predicting these conceptualizations of use? These are but a few questions, that if pursued, would result in the emergence of the blue ocean ideas to which Straub (2009b) refers. We note that some recent work has started to examine different types of use and even its consequences (see Sykes and Venkatesh in press; Venkatesh et al. 2008), which we view as a positive step in helping open up new productive areas of research in the broad theoretical domain.

In addition to use, others have already made contributions to the stream by reconceptualizing other adoption-related constructs. Examples of this work include Schwarz and Chin (2007) who called for researchers to rethink the very idea of acceptance and Karahanna et al. (2006) who called for a reconceptualization of the compatibility construct. Likewise, Compeau et al. (2007) refined the conceptualization of perceived characteristics of innovations from Moore and Benbasat (1991). Taken together, this is an important and fruitful direction as it helps sharpen the definitions and measurements of constructs known to be important within the stream of research. Not only will this in turn result in better prediction of key outcomes, but it also offers the potential to provide greater richness and clarity in our explanations.

38.3.2 Technological Layer

Pushing beyond the inner layer of existing models in our framework, we believe that, at the technological layer, theorizing about newer, more complex types of systems is another fruitful avenue for new research. As an example, one type of system that researchers have successfully studied to date with a strong theoretical grounding is recommendation agents (see review in Xiao and Benbasat 2007). The collection of works examines various design characteristics that are unique to the context of recommendation agents and their impact on key evaluation criteria (Hevner et al. 2004; Komiak and Benbasat 2006; Wang and Benbasat 2005). Other such investigations have included collaborative systems (Brown et al. 2010), mobile data services (Hong and Tam 2006; Thong et al. 2011; Venkatesh et al. 2012), and protective ITs (Dinev and Hu 2007; Johnston and Warkentin 2010; Liang and Xu 2009).

Further expanding the idea of the need to look at specific technology characteristics, it is certainly true that one of the most significant changes in the last several years with respect to technology itself lies in the sheer complexity of modern technological systems. Interestingly, many of the technological systems studied in early technology adoption research were fairly simple, individual-level productivity tools. More recently, the implications for the use of more complex enterprise-wide systems that can span business units within the organization and even across organizational boundaries have been studied (Grewal et al. 2007; Karimi et al. 2009). Although researchers have begun to study the impacts of such systems, they are still typically conceptualized as a "black box" (Beaudry and Pinnsoneault 2005; Morris and Venkatesh 2010), suggesting the need for more detailed theorizing around the nature of new technologies themselves. Clearly, these new systems have the potential to push the limits of our existing technology adoption theories. Although some elements of prior research findings may indeed hold in the context of complex systems—e.g., perceived usefulness will likely continue to be a driver of intention to use in these systems—it is also likely that complex systems will provide an opportunity for deeper theorizing about technologies, their implementation in organizations, and challenges associated with deploying such complex systems (see Boudreau and Robey 2005). As complex technologies will increase the interdependence among users both for information *in* the system and also for help *using* the system, they may increase the range of relevant independent and dependent variables of interest. This, in turn, will give rise to the need to use richer theoretical perspectives, such as social networks and multiple levels of analysis, which are discussed later in this chapter. Finally, complex technologies that integrate various business processes are in keeping with current phenomena and will extend the boundaries of existing models and may call for more sophisticated models (see Sambamurthy 2005; Weber 2003).

38.3.3 Individual Layer

38.3.3.1 Individual and Job Characteristics

Working outward in the framework to move beyond the existing models and technological layers, in organizational settings, it is clear that understanding the influence of both individual characteristics and job characteristics as technology adoption determinants also holds great promise (Morris and Venkatesh 2010). Specifically, moving beyond "technocentric" outcomes, such as use, expands the nomological network of relationships and creates a broader understanding of the implications of technology adoption. Such work is responsive to the suggestions of Delone and McLean (1992, 2003) who have specifically cited the importance of considering other metrics of system success, such as individual and organizational impacts. We extend their idea by suggesting that, within our framework, a similar case could be made on the predictor side as well.

Although research in psychology predicts many beliefs and behaviors using personality (Funder 2001), only limited technology adoption research has studied such constructs in much depth beyond technology-related personality traits, such as computer playfulness, computer self-efficacy, computer anxiety, and personal innovativeness with information technology (see Agarwal and Prasad 1998; Compeau and Higgins 1995a,b; Venkatesh 2000; Webster and Martocchio 1992). One notable and important exception is Devaraj et al. (2008). We believe that further work that studies the role of personality both as an antecedent and as a moderator could greatly enhance the predictive validity of existing models by helping organizations identify individuals with specific personality profiles that can help promote the use, success, and diffusion of technologies. Such work might include, but is not limited to, the big five (see Costa and McCrae 1992), locus of control (see Rotter 1954), and goal orientation (see Dweck 1986).

Just as personality would provide a better representation of the person, consideration of job characteristics can provide a greater understanding of the situational circumstances of employees. Surprisingly, few (if any) technology adoption studies have considered job characteristics or other job-related factors in predicting technology adoption decisions (see Venkatesh et al. 2003) as a means to advance our understanding. The job characteristics model (JCM; Hackman and Oldham 1976) and the demand–control model (Karasek 1979) offer useful ways to consider new theoretical perspectives that can be leveraged to study the impacts on technology adoption decisions (see Morris and Venkatesh 2010).

38.3.3.2 Job Outcomes

On the "downstream" side of the framework, outcomes, such as job satisfaction, organizational commitment, job performance—particularly objectively rated performance that avoids the common method variance concerns articulated in Straub and Burton-Jones (2007)—and other job outcomes that are of interest to employees and organizations should be integrated into technology adoption models to extend our understanding of the influence of use within the organization. Such research also has the potential to influence organizational behavior research by refining models of constructs like job satisfaction to encompass technology-related constructs as predictors that are especially important given the central role that technologies play in most jobs today (Herold et al. 2007). This would be particularly pertinent to organizational change interventions where both new business processes and new technologies are introduced concurrently as is often the case with technologies, such as enterprise resource planning systems (see discussion under the technological layer of the framework). In sum, we call for studies to help build a comprehensive nomological network of relationships that incorporate a richer, broader integration of upstream and downstream constructs that are related—yet distinct—from the traditional determinants and outcomes of technology adoption decisions.

38.3.4 Organizational Layer

38.3.4.1 Social Networks

Moving outward in the framework beyond internal, individualized theoretical layers to "extra-individual factors" is a potential avenue for further exploration. Given that the space of theoretical perspectives is vast, we provide one illustration of a promising avenue (among many possible avenues)—namely, social networks.* Traditional models of adoption and use have often (but not always) included a construct meant to capture the impact of social factors. Sometimes called subjective norm or social influence, this construct captures the degree to which referent others influence an individual's intention to use (or not) the system in question (Taylor and Todd 1995; Venkatesh and Davis 2000; Venkatesh et al. 2003, 2012). However, despite its conceptual importance, the role of others in influencing individuals to adopt new technologies has been inconsistent. Researchers have identified a series of moderating influences, such as gender, age, voluntariness, and experience (Venkatesh et al. 2003) that might clarify the role that social influence plays. The next steps in this area should focus on examining the problem using an extra-individual theoretical lens, such as that available via social networks theory.

Social networks have been used to explain a wide array of behaviors in organizations including early promotion, career mobility, adaptability to change, and supervisor ratings of performance (Burt 1992; Carroll and Teo 1996; Gargiulo and Benassi 2000; Podolny and Baron 1997). Further, within a more technology-centric context, research on social networks has found that centrality in a workflow network is positively associated with supervisor ratings in high-technology companies (Mehra et al. 2001). It also has discovered that individuals are typically more reliant on individual relationships for finding new information (e.g., about technologies) rather than organizational databases or other media including Intranets or the Internet itself (see also Borgatti and Cross 2003; Davis et al. 2009).

Despite the positive individual (and by extension, organizational) performance benefits associated with the appropriate leveraging of social networks, however, the role of social networks, including their size, structure, and nature of the relational ties has not been fully leveraged within the technology adoption research stream. One recent paper that offers a promising look at ways to incorporate social network theory, method, and analysis is Sykes et al. (2009), where network constructs were shown to explain significant additional variance in system use beyond the typical predictors studied in technology adoption research. Other forthcoming research leveraging social networks to better understand the impacts of an implementation include Sykes et al. (in press) and Sykes and Venkatesh (in press).

We contend that social networks represent one theoretical paradigm that may be useful to understanding the role of others in influencing use in a general way as well as gaining a deeper understanding of *which* others inside or outside the organization are the most important, and perhaps even *why* they are important. Once again, we must note that we are not advocating a straight application of social network theory and findings to technology adoption, but rather, we hope researchers will draw on it as a new lens for developing a deeper understanding of behavior and as a mechanism for considering more deeply the *what, how, why, who, where,* or *when* questions that remain relevant for technology adoption and use in today's organizations.

38.3.4.2 Organizational Units†

There are other potential avenues for productive technology adoption research that mandate theorizing beyond the individual level of analysis. For example, Lucas et al. (2007) call for multilevel approaches

* Here, we use the term to refer to the scientific domain around social network theory, method, and analysis techniques—this should not be confused with the emergent popular applications, such as Facebook. Applications such as Facebook can and are used to develop and maintain social networks.

† The authors thank Dr. Likoebe Maruping for his advice on the integration of technology acceptance research with research on teams.

that account for the influence of factors across different levels of analysis. Although there has been research at different levels, they have seldom been integrated. Individuals' adoption and use of technology are often embedded in a social context and, thus, are open to influence by factors that are not currently accounted by an individual level of analysis (see Sarker and Valacich 2010; Sarker et al. 2005). As organizational researchers have noted, microphenomena in organizations and other social systems are embedded within macrocontexts (Kozlowski and Klein 2000). Hence, *meso* theories, which cross multiple levels of analysis, are necessary in order to advance our understanding of organizational phenomena (House et al. 1995). Unit-level factors (e.g., organizational, subdivision, functional, group) could and should be incorporated into models of technology adoption. For instance, within organizations, job types, skills, and the centrality or necessity of technology to the work differ across functional units. Multilevel models can capture the nature of these differences and how they affect individual adoption of organization-wide systems, whereas more sophisticated statistical techniques (which will be explicated in more detail in the methodological layer discussion) can be employed to help analyze such multilevel data (Bryk and Raudenbush 1992; Hofmann 1997).

Once again, to provide an illustrative example of how our framework might be applied in this context, one area that could benefit from a multilevel perspective on technology adoption is research on virtual teams. Much of the research on virtual teams has focused on how information and communication technologies (ICTs) support specific team processes (Dennis and Kinney 1998; Dennis et al. 2008; Nicholson et al. 2006; Powell et al. 2004; Sarker et al. 2005). Virtual teams need to be deliberate in their selection of technology to facilitate task completion (Maruping and Agarwal 2004); however, there is still a need to understand the processes through which the adoption of specific ICTs occurs. Maruping and Agarwal (2004) point to a need for future research to examine how individual differences (e.g., computer anxiety, remote work efficacy) affect virtual teams' choice of ICTs. Reciprocal cross-level models, such as those suggested by Griffin (1997), could be used to model bottom-up processes fostered by individual differences as well to examine how the resulting team interactions influence individual intention to adopt a specific ICT. In sum, the development and testing of such models would provide a richer understanding of the dynamics affecting the adoption of technology in situations that extend beyond the scope of the individual.

38.3.5 Societal Layer

38.3.5.1 Beyond Organizations

There has been a good bit of recent research on nonorganizational (e.g., household) use of technologies (Brown and Venkatesh 2005; Venkatesh and Brown 2001). Other focal areas of study for technologies typically used outside of the organizational context in recent years have been e-commerce (Pavlou 2003; Pavlou and Fygenson 2006; Pavlou et al. 2007) and m-commerce (Mathew et al. 2004; Sarker and Wells 2003; Venkatesh and Ramesh 2006) and other societal-level effects (Hsieh et al. 2008, 2010). The importance of extra-organizational use is only likely to increase in the coming decades. The emergence of social media (e.g., Facebook) makes our need to reexamine the application of existing theory and to consider new theoretical perspectives quite important (Gallaugher and Ransbotham 2010; Kane 2011; Kane et al. 2009).

38.3.5.2 Beyond North America

Clearly, most contemporary technology adoption models have been developed, tested, and subsequently applied in North America. Despite new technologies reaching developing and even underdeveloped countries, our understanding of their adoption, use, and impact in these countries is remarkably limited. Although a few studies in IS have examined cultural differences, several practical and theoretical questions regarding the influence of culture on technology adoption and use remain unanswered (Karahanna et al. 2000, 2005; Straub et al. 2002). Culture, environment, and public policy are among

the factors that will almost surely play a significant role in adoption; yet, our understanding of their influence is limited. Importantly, there have been a few studies that have laid the groundwork for future investigations of culture and adoption (Bajwa et al. 2008; Cyr 2008; Gefen and Straub 1997; Sia et al. 2009; Srite and Karahanna 2006). In light of the spread and infusion of technology to new contexts, studies that further explore the boundary conditions around current models of adoption will be particularly useful. For example, some of the questions that are worthy of additional study may include: Is there cross-cultural generalizability for the models developed primarily in North America? Are there any omitted variables as we move the models to non-North American settings?

Complicating matters further, there are several specific methodological idiosyncrasies in cross-cultural research that are largely different from intracultural research that could potentially change the nature of results obtained in prior studies. For example, there is a high level of construct, method, and item nonequivalence across different cultures that raise questions about the generalizability of prior findings to new settings (see Johns 2006 for a detailed discussion about how different contexts, such as culture, can cause various changes to our theory and empirical findings). There are also several regional, ethnic, religious, and linguistic differences within each culture suggesting that examining culture as a phenomenon in its own right is required. As before, we would like to note that simply examining any question or model in a new cultural setting does not fit the bill of a substantive contribution. Rather, such investigations must start begin from a strong theoretical foundation, grounded in the unique and important psychological, environmental, or other social mechanisms relevant to the cultural context of study (see Venkatesh et al. 2010).

38.3.6 Methodological and Analytical Layer

38.3.6.1 New Method: Agent-Based Modeling

Despite the progress in technology adoption research, there are several puzzles and inconsistencies that remain that may be an artifact of the methodological approaches used in contemporary adoption research. Why do some technologies that would appear to an external observer to be useful and easy to use so often fail to garner the acceptance of target users (Markus and Keil 1994)? Why do some technologies lacking true usefulness so often become widely accepted (Davis and Kottemann 1995)? Why do some promising technologies gain initial adoption, only to fall by the wayside over time (Shapiro and Varian 1999)? More generally, why do technologies sometimes exhibit oscillating patterns of adoption (Maienhofer and Finholt 2002)? Technology adoption research to date has been unable to solve these puzzles.

To overcome these limitations, we propose the use of ABM methodologies that offer key complementary strengths (see Railsback and Grimm 2011) to the narrative, mathematical theories, and methods traditionally employed in technology adoption. Research on organizational adoption of innovations, such as total quality management (Repenning 2002), quality circles (Strang and Macy 2001), downsizing (Rosenkopf and Abrahamson 1999), and production technologies (Bullnheimer et al. 1998), have all found ABM valuable in providing insights into the dynamics of adoption beyond those afforded by more traditional methods (see also Latane 1996). A major reason for the insights is that ABM was used to incorporate both rational and social forces within a common modeling paradigm. Rational and social explanations have often been regarded as competing accounts for technology adoption (Kraut et al. 1998b; Schmitz and Fulk 1991). Even though neither is able to single-handedly explain technology discontinuance decisions, when combined, they can account for fad-like waves of adoption and rejection (Strang and Macy 2001). These initial applications of ABM to the study of organizational adoption illustrate how the complex interplay of various social influences give rise to *unintuitive* emergent global behavior across a population of firms. Similar advantages are expected to accrue through the use of ABM to specifically study individual-level adoption of technology. In a similar fashion, the dynamic complexity revealed by these organizational adoption studies portend that ABM can be used to solve

similar challenges in studying technology adoption at the individual and group layers of the framework.* ABM allows for simulations that have varying time granularity as well as detailed models of influence, thus allowing for a rich understanding of emergent phenomena that extends well beyond what exists in current models.

38.3.6.2 New Analytical Technique: Polynomial Modeling and Response Surface Analysis

In addition to new theoretical approaches and new methods, new analytical techniques might be utilized in order to bring new insights or perspectives to technology adoption and use. One approach—common in the management literature—that has not been employed to its full potential in technology adoption research is polynomial modeling and associated response surface modeling. Rather than being limited to the use of "best fit" linear models, the use of polynomial models allows researchers to capture more complex and dynamic behavior that, in the past, has been difficult to explore analytically. Although an in-depth discussion of polynomial modeling is beyond the scope of this chapter, the use of polynomial models and the related use of response surfaces can be used to plot two independent variables in relation to a dependent variable on a three-dimensional graph (see Edwards 1995; Edwards and Harrison 1993; Edwards and Parry 1993 for an extended discussion on polynomial models and response surface analysis). Such a technique is better able to capture the complex and nonlinear effects of change (e.g., the shift between pre-implementation and post-implementation attitudes) and avoids many of the methodological problems associated with difference scores that are often used such as weak reliability, conceptual ambiguity, and encapsulation of confounding effects of the independent variables on the components of the difference (Edwards 1995).

With respect to technology adoption and use, polynomial response surface modeling might be applied in a number of ways. First, although some have recognized the potentially important nature of changes in perception or use over time, most existing models have either attempted to control for prior perceptions (e.g., perceptions of usefulness at time 1 are used as a control on those at time 2), or have conceptualized the change as a single (new) construct meant to capture the dynamics of change. Either technique, although understandable given prior analytical constraints, reduces potentially nonlinear, multivariate relationships into a linear, univariate one, thereby suppressing a number of potentially interesting elements that may contribute to changing patterns of adoption and use over time.

Two examples of how polynomial response surface modeling might be applied to technology adoption and use may be helpful to illustrate its benefits. First, in studying some of the downstream consequences of use, one might examine how both pre-adoption and post-adoption perceptions combine in novel ways to influence user attitudes and/or performance. Such an approach would plot pre- and post-adoption measures on the *X* and *Y* axes, respectively, with the dependent variable of interest (say, performance) on the *Z* (vertical) axis. Another approach, consistent with the theoretical underpinnings of expectation–confirmation models, would be to measure pre-implementation expectations and post-implementation beliefs together (*X* and *Y* axes) to predict downstream perceptions or use (*Z* axis), rather than relying on a single construct, such as confirmation or disconfirmation, that typically had to be used in prior research to capture the differences (Bhattacherjee 2001; Bhattacherjee and Premkumar 2004). Venkatesh and Goyal (2010) and Titah and Barki (2009) are exemplars that use this approach to model nonlinear effects as a means to advance our understanding of technology adoption (see also Brown et al. 2012; Brown et al. in press). New work could build on these recent examples in order to identify opportunities for deeper theorizing about how shifts in constructs, rather than absolute levels themselves, might influence important outcomes such as performance or satisfaction, while simultaneously challenging the assumptions of linearity that underlie most current theorizing.

* Note that the methodological and analytical layer spans the other layers of the framework in Figure 38.1.

38.3.6.3 Qualitative Research

We believe that qualitative research methods and associated approaches to interpret data hold particular promise for breaking the shackles of normal science in which technology adoption is currently situated. Qualitative research blends induction with search for novel insights that hypothetico-deductive approaches that have dominated this stream lack (see Locke 2007). Qualitative research has a rich tradition in business management research, with many well-known papers that present guidelines on how to do qualitative research (Benbasat et al. 1987; Lee 1989). Within the technology adoption stream, there have been some innovative papers that have brought to the fore new ideas, concepts, mechanisms, and even problems that were previously undiscovered (Sarker and Lee 2002, 2003, 2006; Sutanto et al. 2008; Wagner and Newell 2007). Taking the cue from these exemplars, we believe that the qualitative approach is underrepresented in technology adoption research and that researchers in the stream can further leverage these methodologies across each of the layers of our framework (Figure 38.1) to help identify new constructs, develop new theory, and create blue ocean ideas, consistent with the ideas of Straub (2009b). Further, the employment of multiple methods can lead to rich insights that any single method cannot provide (see Venkatesh et al. 2013).

38.4 Conclusions

In this chapter, we have made a case for the continued relevance and vitality of the technology adoption research stream. In so doing, we acknowledge many of the criticisms that have recently been levied at research in the area and agree with the broad conclusion that this important stream of research runs the danger of becoming stagnated unless we, as a community of researchers, can harness our creative talents to reinvigorate research in the domain. Although challenging, the problem remains critically important to research and practice, and we have a responsibility to conduct value-added studies that bring new scientific knowledge into the fold. Within the context of our critique and assessment of research on technology adoption, we have offered a new framework that we hope serves as a useful starting point for motivating additional work in the area that pushes all of us interested in the area out of our "comfort zone," beyond "normal science," and toward a period of research that pushes the boundaries of our existing knowledge through perhaps a scientific revolution that comes from breaking away from existing paradigms. In doing so, rather than declaring technology adoption research "dead" and having this chapter serve as its epitaph, we hope the thoughts and commentary here instead bring to mind the famous adages from such disparate personalities as Mark Twain and Steve Jobs indicating that accounts of one's death—in this case, the technology adoption research stream—are greatly exaggerated. Indeed, we hope that our ideas here might serve a useful role in revitalizing one of the most mature streams in business management research. In doing so, we hope to bring an end to the debate on the merits of TAM and its derivatives per se and, instead, motivate proponents and critics of the current state of the research stream (and we count ourselves as both) to extend technology adoption theory to new frontiers of knowledge.

Computer Self-Efficacy

George M. Marakas
Florida International University

Miguel I. Aguirre-Urreta
DePaul University

Kiljae Lee
University of Kansas

39.1 Introduction

Every year, both organizations and their employees invest a significant amount of resources in training and development programs, in the hope that these will have an important impact on employee growth and ultimately on organizational performance. Among the many skill sets, computer skills are the most frequent type of training provided by organizations (Yi and Davis, 2003). Rooted in Social Cognitive Theory (SCT) (Bandura, 1997), computer self-efficacy (CSE), generally defined as a "judgment of one's capability to use a computer" (Compeau and Higgins, 1995b), has been repeatedly identified as a key outcome of training, mediating the effects of a number of influences on performance, such as training treatments, past experience and demographic variables (Marakas et al., 1998), or personality characteristics and other individual differences (Johnson, 2005), and affecting performance both directly and through its impacts on different motivational and affective mechanisms. Individuals displaying high levels of CSE are expected to be more focused and persistent, put more effort into their endeavors and be more committed to achieving their goals, be more able to cope with negative feedback, and be generally less anxious about completing the task (Marakas et al., 1998).

In addition, there is an important literature base, both in information systems and in other reference and related disciplines, bearing on the issue of self-efficacy modification and development. Among those examined, programs based on behavior modeling, i.e., observing someone perform a target behavior and then attempting to reenact it, have been shown to be particularly effective (Johnson and Marakas, 2000). Further, such research has become the focus of more detailed examinations into the processes by which learning is affected (Yi and Davis, 2003). Research has also focused on collaborative learning, either by itself or in combination with other approaches, such as behavior modeling (Davis and Yi, 2004; Keeler and Anson, 1995). Overall, this rich and growing stream of research has made CSE an attractive target for the implementation of treatments and interventions.

In general, it is then possible to build a theoretical chain of reasoning connecting computer training interventions with ultimate task performance. Indeed, researchers from both the academic and applied communities often use this presumed state of affairs as justification for the importance of furthering our understanding in this realm. For example, Compeau and Higgins (1995a) argued that user training was a widely recognized factor contributing to productive use of information systems in organizations. Yi and Im (2004) highlighted computer task performance as a major contributor to end-user productivity, while Yi and Davis (2003) remarked that effective computer training is a major contributor to organizational performance.

Given the ubiquitous nature of computers in the workplace, the home, and our daily lives, it may be tempting to assume that because we are immersed in using computers and their associated technologies, we all possess the appropriate level of CSE—that is to say, "we all have it." As such, this temptation results in a declaration that while CSE was important 15–20 years ago, it is far less so today. It is our belief that as computers, and IT in general, become more and more pervasive, CSE stands to become more, and not less, important in the future. Both the academic and applied communities are far from being done with their focus on CSE. Both stand at a threshold where academic research can now begin to bring useful understanding to the goal of achieving a high computer literacy and skill set in the workplace and our society.

39.2 Underlying Principles

The primary foundation for the CSE construct is rooted in SCT (Bandura, 1997) and its major theoretical concepts and relationships. Given the very rich and complex nature of this framework, it is unlikely that this brief summary will do it justice. Thus, the reader is referred to the work of Bandura (1986a, 1997) himself for a full account. SCT and its central variable, *self-efficacy*, have proven to be an extremely popular basis for research in a number of distinct areas, such as academic and health behaviors, management and organizational psychology, leadership, training, negotiation, and career development, to name just a few. By one account, more than 10,000 investigations involving this theory have been conducted since it was first formulated more than 25 years ago (most notably, in 2004 alone, an average of 1.67 articles per day were published on self-efficacy) (Judge et al., 2007).

In contrast to unidirectional models of causality that attempt to explain human behavior as being controlled either by environmental influences or by internal dispositions, SCT explains functioning in terms of a *triadic reciprocal causation* between behavior, cognitive and other personal factors, and the external environment. This model of reciprocal determinism is depicted in Figure 39.1.

The model is argued to be deterministic in the sense of the production of effects by events, rather than suggesting that actions are completely determined by a prior sequence of causes independent of the individual and his or her actions. Given that behavior is jointly determined by a number of factors operating interactively, effects produced by particular events are considered to be probabilistic, rather than inevitable, in this conceptual system.

Another important aspect of Figure 39.1 is the postulated reciprocality between the *environment*, *cognitive and personal factors*, and *behavior*. While the underlying logic states that these three factors influence each other in a bidirectional relationship, it neither does assign equal strength to the different sources, nor does state that influences occur simultaneously. Rather, *time* is involved in the activation of causal factors, their influence on others, and the emergence of reciprocal influences. Given this bidirectionality, individuals are considered to be both the products and the producers of their environment (Wood and Bandura, 1989b).

Self-efficacy beliefs are thus concerned with an individual perception of capability to mobilize the motivational and cognitive resources and courses of action needed to exert control over events of personal relevance. This complements true skills and capabilities, in that it stimulates their use under difficult and stressing circumstances. Individuals with the same level of skill may then perform poorly, adequately, or extraordinarily depending on the effects their personal efficacy beliefs have on their motivation and problem-solving efforts (Wood and Bandura, 1989b). Thus defined, perceived self-efficacy is

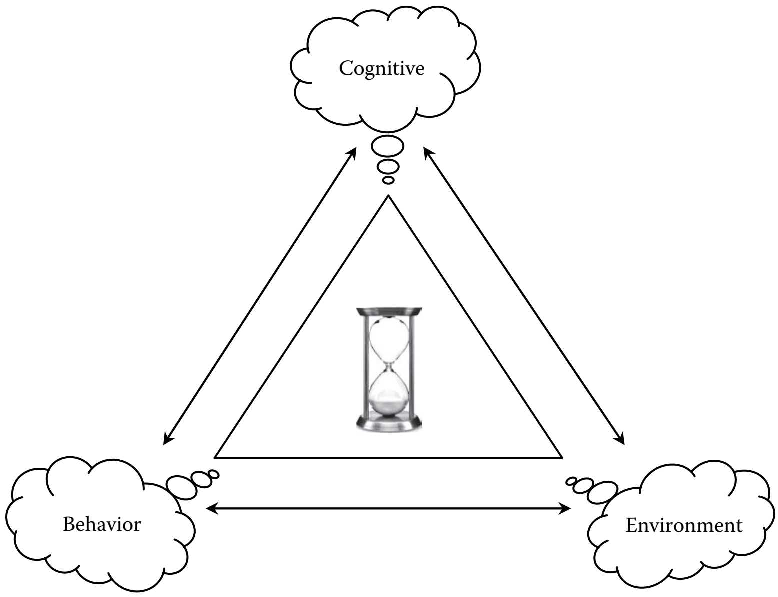

FIGURE 39.1 Triadic reciprocal determinism.

a generative capability in which a number of subskills involving cognitive, social, emotional, and behavioral aspects of functioning must be organized and orchestrated effectively to serve certain purposes.

39.2.1 Dimensions of Self-Efficacy Beliefs

All self-efficacy beliefs vary along three important dimensions (Bandura, 1997). First, they differ in *level*; efficacy beliefs of individuals may be limited to simple task demands, extend to moderately complex ones, or encompass the most taxing performance demands within a particular domain of functioning. Thus, efficacy beliefs are not decontextualized traits upon which situational demands operate. Rather, they represent the actual performance requirements for the context under consideration against which efficacy is judged.

Second, efficacy beliefs vary in *generality*. Individuals may judge themselves to be efficacious across a wide range of activities and domains or only within certain specific activities and domains of human functioning. This assessment of generality itself can vary along different dimensions, such as the degree of perceived similarity present in activities, the mode in which capabilities are expressed (e.g., cognitive, affective, behavioral), qualitative features of different situations, and also characteristics of individuals toward whom behaviors are directed.

Finally, self-efficacy beliefs also vary in *strength*; whereas weak beliefs are easily negated by discomforting experiences, individuals possessing strong convictions will persevere in the face of obstacles and difficulties, and will not be easily overwhelmed by adversity. Strength of self-efficacy, however, is not linearly related to choice behavior, since it is postulated that a certain threshold level must be crossed in order to even attempt a certain course of action, and higher levels of self-efficacy would also result in the same behavior being attempted. Strength of efficacy beliefs manifests itself in the greater perseverance, and thus likelihood of success, in the chosen activity.

39.2.2 Primary Sources of Efficacy Beliefs

Following SCT, beliefs of personal efficacy are constructed from four main sources of information relevant for the formation of a judgment about capability for performing a task. Moreover, these sources

are not exclusive of each other, and thus any given influence may operate through one or more of them. However, information that is available but neither processed nor integrated into cognitive thought is unlikely to have any effect on self-referent perceptions. In general, the processing of self-efficacy information depends on two separable functions. The first one relates to the *types of information people attend to and use*; each of the four sources of efficacy beliefs has a distinctive set of indicators and cues. The second function refers to *the rules, processes and heuristics that people use to weight and integrate the different sources of information* (Bandura, 1997).

The most influential source of information affecting efficacy beliefs is *enactive mastery*, e.g., repeated performance accomplishments. While positive mastery experiences serve to increase self-efficacy, negative ones are more likely to debilitate it. These experiences provide the most authentic evidence of whether an individual is able to orchestrate the capacities required to succeed in a particular endeavor. Enactive mastery has a stronger and more generalized effect on efficacy beliefs than any of the other three sources of information. Despite this strength, performance alone does not provide oneself with enough information to judge levels of capability, since many factors having little to do with the latter can have an important effect on performance. Thus, changes in self-efficacy result from cognitive processing of diagnostic information that past performances convey about the capability to effect them rather than the mere act of carrying out an activity. The extent to which performance experiences alter beliefs of self-efficacy also depends on a host of factors such as *preconceptions of capability, perceptions of task difficulty, the amount of external aid received, the circumstances of the performance, the temporal pattern of failures and successes,* and *the process by which these experiences are organized and reconstructed in memory* (Bandura, 1997).

Second, people not only do rely on past experience as the only source of information about their performance capabilities, but also are influenced by *vicarious experiences* obtained from various modeled attainments. Models build beliefs of efficacy by conveying and exemplifying effective strategies to manage a variety of situations. Social comparison processes, such as watching a similar person perform the same or similar task under consideration, also play a role in the effects modeling obtains on self-efficacy, given that human beings partially judge their capabilities in comparison with others. Given that, for most activities, there are no objective measures of adequacy, referential comparisons become very salient. In some cases, performance or social standards are available such that individuals may judge where they stand in comparison with some expected outcome. In others, people seek to compare themselves with similar others, such as coworkers, classmates, competitors, etc., to inform their efficacy beliefs.

Wood and Bandura (1989b) commented extensively on different mechanisms governing modeling processes and on their primary importance for the development of competencies through targeted training interventions. Indeed, a significant portion of research involving self-efficacy, and CSE in particular, as reviewed later, has been conducted in the context of training programs. In reference specifically to vicarious experience, four different processes govern this source of efficacy belief formation.

First, *attentional processes* play an important role in determining what people selectively observe in the large variety of modeling influences available to them and what information is extracted from those that are observed. The logic is that people cannot be influenced by observed performances if those cannot be remembered. Next, *representational processes* involve the transformation and restructuring of remembered information about events into the form of rules and conceptions. Retention of this information is greatly improved when individuals symbolically transform the modeled information into mental codes and then rehearse the coded information. During the third component of behavior modeling, *behavioral production processes*, those symbolic conceptions are now translated into appropriate courses of action, through a matching process in which guided patterns of behavior are enacted and the adequacy of these actions are contrasted against the conceptual model, leading to an iterative process by which individuals adjust their behavior in order to achieve correspondence between actions and conceptions. Finally, *motivational processes* involve three major types of incentive motivators. Individuals are more likely to enact modeled strategies

that produce valued outcomes and set aside those with unrewarding or punishing effects. People are also motivated by the success of similar others, but are discouraged from pursuing behaviors that have been known to result in negative consequences. Personal, self-produced standards provide yet another source of performance motivation.

Verbal persuasion represents the third important source of information involved in the development of efficacy belief, but lags behind enactive mastery and vicarious experiences with regard to the strength by which it is able to do so. While verbal persuasion alone may have a limited effect in creating enduring efficacy beliefs, faith in one's capabilities as expressed by significant others, particularly during times of doubt or despair, can have a substantial effect with respect to the mobilization and maintenance of effort. Persuasion has its greater impact on those individuals that, for whatever reason, already believe they can produce certain effects through their actions. The raising of efficacy beliefs to unrealistic levels, however, is likely to result in a failure that would not only undermine future conceptions of self-efficacy, but also discredit the source of information. The degree of appraisal disparity, i.e., how different one's own beliefs are from what people are told, is an important contingency on the effects of social persuasion. While social appraisals that differ markedly from judgments of current capability may be considered believable in the long run, they are unlikely to be acted upon on the short term. Persuasive appraisals are more likely to be believed when they are only moderately beyond what individuals can do at the time.

Lastly, people rely on the information provided by physiological and emotional states in assessing their capabilities. They read their *emotional arousal* and tension as signs of vulnerability to poor performance. Even before CSE had become the subject of focused research, computer anxiety (Heinssen et al., 1987) had already attracted the interest of the information systems community. Because high arousal can debilitate performance, people are more inclined to expect success when they are not undermined by aversive arousal. Treatments that reduce emotional reactions to subjective threats through mastery experiences can help increase beliefs in coping efficacy and correspondingly improvements in performance. Thus, the fourth major way of altering efficacy beliefs is to enhance physical status, reduce stress levels and negative emotional influences, or alter dysfunctional interpretations of bodily states.

39.2.3 Cognitive Processes

Efficacy beliefs affect thought patterns that can either enhance or undermine performance, and these influences take various forms. People with a high sense of efficacy tend to take a future time perspective in structuring their lives, and since most courses of action take initial shape in thought, these cognitive constructions then serve as guides for future actions. Strong efficacy beliefs also affect perceptions of situations as presenting realizable opportunities.

Those who judge themselves inefficacious, on the other hand, construe uncertain situations as risky and visualize scenarios involving failure. Perceived self-efficacy, and this process of cognitive simulation, also affects each other bidirectionally, positive cognitive constructions in turn strengthening efficacy beliefs. A major function of thought is to enable people to both predict the likely outcomes of different courses of action and create the means to exert some degree of control over those (Bandura, 1997).

People draw on their existing knowledge in order to construct and weigh options, integrate predictive factors into rules, test and revise judgments against the results of actions, and also remember which factors were tested and how well those performed. A strong sense of efficacy exerts a powerful influence on self-regulatory cognitive processes and supports the ability to remain task oriented in the face of causal ambiguity, personal and situational demands, and judgment failures that can potentially have important repercussions for the individual. Results from a series of experiments provide strong support for the diverse set of influences that alter efficacy beliefs, and those in turn influence performance attainments through their effects on goals and efficiency of analytic thinking.

39.2.4 Motivational Processes

Bandura (1997) argued that most human motivation is cognitively generated, e.g., people motivate themselves and guide their actions through exercise of anticipation and forethought. Human beings form beliefs about what they can and cannot do, anticipate the likely positive or negative consequences of different courses of action, and then set goals and make plans to realize valued outcomes and avoid the unpleasant ones. It is possible to distinguish three different bodies of theory on motivational processes, built around *causal attributions, outcome expectancies,* and *cognized goals*. Efficacy beliefs play a central role in all of them.

Retrospective judgments of the causes of past performances are postulated to have a motivational effect according to *attribution theory*. Individuals who attribute past successes to personal capability and failure to insufficient effort will undertake more difficult tasks and persist longer in the face of negative feedback, since they perceive outcomes as being a function of how much effort is spent in pursuing them. In contrast, those who ascribe failures to situational determinants will display reduced interest and abandon courses of action in the face of difficulties. Results from extensive research indicate that causal attributions can indeed influence future performance, but that the effect is fully mediated by their influences on beliefs of self-efficacy. For instance, attributions of past success to one's ability heighten beliefs of personal efficacy, which in turn influence future attainments.

SCT, however, presents a more comprehensive picture of the mechanisms by which past performance influences self-efficacy than does attribution theory, which is generally limited to considerations of effort, ability, task difficulty, and chance. People also consider the situation under which they performed, the amount of assistance received, and the rate and pattern of past successes as valuable information that is integrated into judgments of capability. In addition, efficacy beliefs can also bias causal attributions. Thus, efficacious individuals are more likely to attribute failures to insufficient effort or environmental impediments, whereas those with a low sense of efficacy attribute them as arising from a lack of ability. Performance feedback that is inconsistent with perceived self-efficacy is dismissed as less accurate and more likely to be attributed to extraneous factors.

Individuals also motivate themselves by considering the *outcomes* they expect to accrue from following a given course of behavior. Expectancy-value theory essentially predicts that motivation to perform an activity is the result of expecting that doing so would secure specific outcomes and that those outcomes are highly valued by the person considering the performance. Bandura (1997) notes, however, that people are less systematic in their consideration of potential courses of action and in their appraisal of likely outcomes than expectancy-value models would suggest and argues that individuals act on their beliefs about what they can do as well as on their beliefs about the likely effects of their actions. A diminished sense of efficacy can then eliminate the potential allure of certain outcomes if individuals believe that they cannot successfully perform the actions that would lead to them. In activities where outcomes depend on the quality of the performance, efficacy beliefs thus determine which outcomes will be foreseen, and expected outcomes contribute little to future performance when efficacy beliefs are statistically controlled for in research models.

Lastly, behavior is also motivated and directed by *goals* that result from forethought and self-regulatory mechanisms. Cognitive motivation, based on the pursuit of goals or standards, is further mediated by different types of self-influences—affective reactions to performance. Such self-influences include anticipated satisfaction from fulfilling valued standards or self-dissatisfaction with poor performance, perceived self-efficacy for goal attainment (which influences which challenges to undertake), how much effort to spend in the endeavor and how long to persevere in the face of difficulties, and adjustment of standards in light of past attainments (which depend on the construal of the pattern and level of progress being made).

39.2.5 Affective Processes

Efficacy beliefs also play a pivotal role in the regulation of affective states, impacting the nature and intensity of emotional experiences through the exercise of personal control on thought, action,

and affect. In the first case, efficacy beliefs create attention biases and influence whether and how events are construed, represented, and retrieved in ways that are emotionally benign or perturbing. Also perceived cognitive abilities influence the control of negative trains of thought that intrude in the flow of consciousness and distract attention from the task and situation at hand. In the action-oriented mode of influence, efficacy beliefs support courses of action that transform the environment in ways that improve its emotional potential. The affective mode influences self-efficacy to negatively affect aversive emotional states once they have been aroused.

39.3 General versus Specific Computer Self-Efficacy

Consistent with the root theory, SCT, upon which the CSE construct is based, we recognize that CSE is a multilevel construct. CSE can be, and has been, operationalized at both the general computing behavior level and at the specific computer application level. Thus, GCSE refers to *an individual's judgment of computing capability across multiple computer application domains* whereas CSE refers to *an individual's perception of efficacy in performing specific computer-related tasks within the domain of general computing*. Research has shown that these two constructs are correlated but distinct (Johnson and Marakas, 2000).

Figure 39.2 presents a theoretical model describing the relationship between GCSE and CSE as well as how the two constructs uniquely affect both task-specific and overall computing performance. Each CSE perception is the major determinant of its associated task performance, and GCSE is the major predictor of general computer performance. Each computer user can have a different set of CSE perceptions related to multiple domain-related experiences that affect the formation of GCSE and can apply different weights to each of them in forming their GCSE perception.

The level of CSE formed at one time further influences the level of subsequent CSE perceptions. Thus, the model explains why two individuals can have the same level of GCSE when their CSEs are different in an application-specific computer domain. It also explains why two individuals can have different levels of GCSE while having similar levels of CSE at the task level. From this, we expect an increase in GCSE as an individual gains experience with different computer applications and computer-related tasks and experiences. We also expect an increasing initial level of CSE for future application-specific tasks over time. Furthermore, the model suggests that particularized measures of CSE will surpass general measures of GCSE in explanatory and predictive power for specific performance as suggested

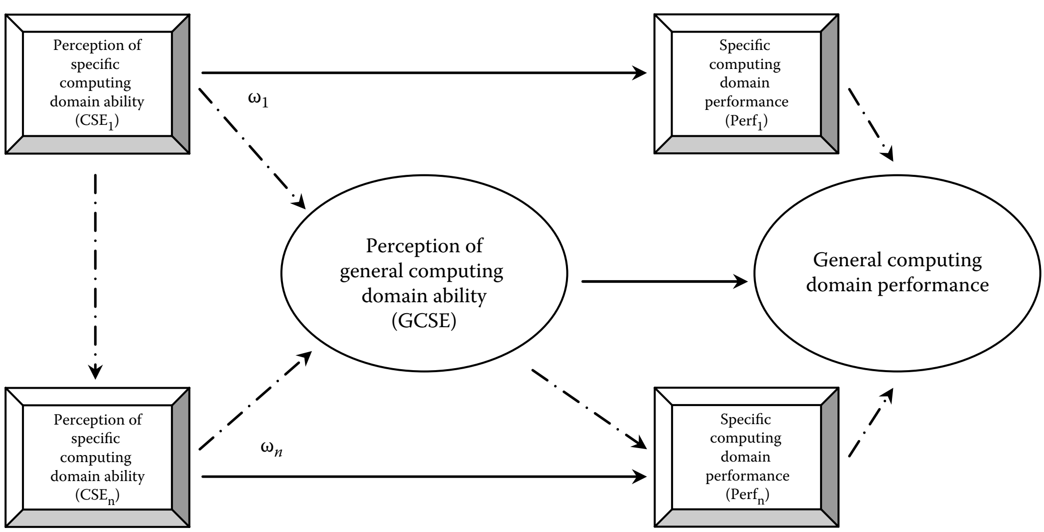

FIGURE 39.2 General computer self-efficacy.

by Bandura (1986a) and Gist (1987) but not for general computing performance. This implies that CSE is a more cost-effective and powerful mechanism to make an impact on user's specific computer performance whereas GCSE is a less malleable but more enduring mechanism over time. This has significant implications for organizational training programs that use CSE formations to assist in performance enhancement within the computing domain.

From an academic perspective, it is important to note that out of the 59 IS papers that used self-efficacy published in the top 4 IS journals from 1985 to 2011, 40 articles chose to employ the GCSE construct while only 19 articles used the CSE construct. This suggests the original premise advanced by Marakas et al. (1998) regarding the need for specific task-related measures of CSE versus simply measuring GCSE has yet to be adopted by the IS research community at large. Additional research is needed to establish the true boundaries of GCSE perception formation such that a generalizable, and reliable, measure of the GCSE construct can be developed.

39.3.1 CSE and Task-Specific Self-Efficacy

Although Bandura (1997) convincingly argued that multiple types of self-efficacy are relevant to performance in any given domain, few studies have examined the joint effects of more than one type on performance (Tierney and Farmer, 2002). Complex organizational tasks generally involve the use of particular means in order to achieve the desired level of performance. However, a mismatch between self-efficacy and performance occurs when only judgments of capability for performing the prescribed means are involved as predictors of performance, since the latter depends also on the particular influence of the selected means and how they relate to task accomplishment (Stajkovic and Luthans, 1998). In particular, Bandura (1997) stated:

> When personal efficacy to perform the prescribed means is used as a predictor in the hypothesized causal model, one is testing not only the predictive power of efficacy beliefs but also the validity of the posited influence of the prescribed means on attainments in the causal model… When the means that produce certain behavioral attainments are only partially understood or have not been adequately verified, efficacy beliefs should be measured at two levels of specificity: efficacy to execute the prescribed means successfully and efficacy to achieve different levels of performance attainments by whatever means people choose to do so (p. 63).

It seems reasonable, given the earlier text, to consider the appropriate positioning of CSE, which is argued to represent the *prescribed means of attainment* (e.g., performing a certain task with the use of computer technologies), in relationship to task self-efficacy (TSE), which represents the more *general level of specificity*. In line with these arguments, Marakas et al. (2007) noted the need to develop complex models of performance that incorporate efficacy estimations of both domain and technical skills, involving the use of multiple instruments. However, there is essentially little existing research (with the singular exception of the work of Looney et al. 2006) that sheds light on the form of the relationship between domain and computing skills and its effects on task performance. In other words, when considering CSE as it relates to a computer-related task, we must not only consider a person's perception of their ability to use a computer to perform the task, but we also simultaneously consider the person's perception of their ability to perform the task. People do not simply use a computer—rather, they use a computer to do something specific. If a person is faced with using an Excel spreadsheet to construct a budget, we must consider their perceived ability to use Excel (CSE) simultaneous with their perceived ability to construct a budget (TSE).

Given this, it is argued that the more specific perception of self-efficacy, one that captures the use of technologies to perform the task, will be most closely related to performance. The next step, then, is to theorize how CSE is related to this intervening construct. Aguirre-Urreta (2008) positions CSE as moderating the effects of TSE on computer-specific task self-efficacy (CSTSE), "an individual's perception of

efficacy in performing a particular task with the support of computer technology" (pp. 84–85). While judgments of capability in both realms are jointly needed to influence CSTSE, TSE is positioned as the main driver of the relationship. Paralleling creativity self-efficacy research, it is argued here that, even in the presence of strong CSE, it would be difficult for an individual to feel efficacious in performing a task when devoid of perceived functional capacity (Tierney and Farmer, 2002). On the other hand, weak computer skills are likely to erode the positive effects that TSE brings to performance.

It is expected, then, that feelings of efficacy to perform a task with the support of technology would be stronger when feelings of adequacy for both functional and technology skills are present. Conversely, when both TSE and CSE are low, it is expected that CSTSE would be low too. As theorized by Aguirre-Urreta (2008), the depiction of TSE as the main driver and CSE as the moderating influence would lead one to expect that in situations where TSE is high and CSE is low, CSTSE would be higher than that in those occurrences when the opposite occurs. Finally, when multiple self-efficacies come into play in predicting performance, it is expected that the more specific and proximal type would account for the direct effects on the dependent variable (Bandura, 1997). This positioning of the CSE construct as a moderating variable is a significant departure from previous research, which commonly positioned the CSE construct as an independent or mediating variable.

39.4 CSE and Performance

Of the myriad of antecedent and consequent relationships that have been empirically employed using the CSE construct, there is extensive support for the relationship between CSE and computer performance, in different contexts and for a variety of software applications (Compeau and Higgins, 1995a; Johnson, 2005; Johnson and Marakas, 2000; Marakas et al., 2007; Yi and Davis, 2003; Yi and Im, 2004). Given the objective of these efforts on isolating the performance effects of this central construct, dependent measures have focused exclusively on syntactic- and feature-based uses of the different software packages involved, most notably productivity suites. As such, these outcomes represent knowledge situated in the first three levels of the hierarchy developed by Sein et al. (1998): syntax (actual language through which a user interacts with the application), semantic (meaning of those commands), and functional (e.g., grouping commands into a task such as creating a document).

On the broader level, decades of research involving the self-efficacy construct and work-related behaviors have generated a rich and extensive literature that would be impossible to review in any comprehensive manner but that is, nonetheless, applicable to the more narrowly focused CSE construct.* Empirical findings have demonstrated the relationship with work performance in a wide variety of settings, such as *idea generation* (Gist, 1989), *newcomer adjustment* (Saks, 1995), *coping with career events* (Stumpf et al., 1987), *creativity in the workplace* (Tierney and Farmer, 2002), *skill acquisition* (Mitchell et al., 1994), and even *seasickness* (Eden and Zuk, 1995), along with the ever-present research regarding *computer-related behaviors* (Compeau and Higgins, 1995a; Gist et al., 1989; Johnson, 2005; Johnson and Marakas, 2000; Marakas et al., 2007; Martocchio, 1994; Martocchio and Judge, 1997; Yi and Davis, 2003; Yi and Im, 2004).

Continuing with the focal area of interest, some of the early work on CSE was conducted by Hill et al. (1987) and by Gist et al. (1989). In the first case, the authors postulated that efficacy beliefs with respect to computers would be important determinants of the decision to use computers in the future and thus a possible avenue through which adoption could be fostered. In particular, they investigated

* The reader is referred to the large-scale meta-analysis conducted by Stajkovic and Luthans (1998). Reviewing in excess of 100 different studies, the authors examined both the general performance effects of self-efficacy and the significant within-group heterogeneity of individual correlations. Overall results from the meta-analysis, exclusive of moderator considerations, indicated a positive and significant correlation of self-efficacy and performance of 0.38 ($p < 0.01$). Further analyses indicated the presence of an interaction between moderators, such that average correlations between self-efficacy and performance were strongest for low-complexity tasks performed in laboratory settings (0.50, $p < 0.01$), and weakest, but always significant, for highly complex tasks assessed in field settings (0.20, $p < 0.01$).

the importance of efficacy beliefs over and above beliefs about the instrumental value of using computers. The underlying rationale for their Study 1 was that perceptions of controllability would have an important impact on whether individuals decided to use computers, separately from whether they believed their use implied any particular positive or negative consequences. It has been noted that, in this regard, self-efficacy beliefs may not be altogether different from perceived behavioral control, as incorporated into Ajzen's Theory of Planned Behavior (see Ajzen, 2002; Terry and O'Leary, 1995). Their results showed that, for both men and women, behavioral intentions to use computers were significantly predicted by both instrumentality and efficacy beliefs, and that behavior, measured as enrollment in classes requiring the use of computers, was significantly predicted by behavioral intentions.

In a second study, Hill et al. (1987) predicted that the same relationships would hold, but after adding previous experience with computers as a covariate with both efficacy and instrumentality beliefs. In addition, the behavior of interest was expanded to incorporate the decision to use technological innovations in general. Using a different subject sample, their results confirmed those discussed earlier, even when controlling for previous experience, measured in terms of the number of times a computer had been used in the past, whether the participants had written a computer program, or used a packaged computer system.

Gist et al. (1989) studied the relative effectiveness of alternative training methods designed to foster self-efficacy and the relationship of these perceptions to performance on an objective measure of computer software mastery. The two chosen training approaches were modeling, where participants watched a video of a model illustrating specific steps needed to perform a task, and a tutorial setting, where participants in the study employed an individual training program that presented concepts similar to those shown in the modeling condition. The authors assessed CSE prior to training as a general variable that attempted to capture the confidence subjects brought to the training sessions, and software self-efficacy, post-treatment, as the focal variable of interest.

Results showed support for the hypotheses that trainees in the modeling condition would develop higher software self-efficacy than those in the tutorial condition and that participants initially low in CSE would report higher software self-efficacy in the modeling compared to tutorial training condition. While the relationship between software self-efficacy and performance was not examined, pretest computer efficacy was significantly related to training performance, thus providing additional support for the efficacy–performance relationship in a computer-related context. In addition, this study represents an early example of the separation between more specific and more general types of computer-efficacy perceptions.

Marakas et al. (1998) proposed a model of the relationship between CSE and performance, discussed previously, which included direct and indirect effects of the former on the latter, in some cases also involving moderated relationships.

Yi and Davis (2003) examined the relationship between self-efficacy and performance as part of their efforts to develop an improved training approach based on behavior modeling and observational learning processes such as attention, retention, production, and motivation. This new model was proposed in order to provide a more detailed account of the mechanisms by which modeling-based interventions enhanced training and thus provide a base for both the evaluation and the improvement of training techniques in the future. Software self-efficacy was measured prior to training, as part of the effort to control for pre-training individual differences, and after the training intervention as one of the main outcomes of the proposed approach, declarative knowledge being the other. Task performance was measured immediately after training and a second time with a 10 day delay in between. Results from PLS analysis show that pre-training self-efficacy is significantly related to the post-training construct. The latter had significant effects on both immediate and delayed task performance, even when declarative knowledge was also included in the analysis. This confirms the role of CSE as both one of the primary determinants of performance and one of the primary outcomes of training interventions.

Yi and Im (2004) studied the relationship between CSE, personal goals, and performance, using data from a software training program. Considering beliefs of efficacy and personal goals is important

because they provide two different, even if complementary, answers to the question of why some individuals perform better on tasks when they are similar in ability and knowledge to others that do not perform as well on the same tasks. Individuals that display higher levels of self-efficacy believe that they can do more with their capacities than others that possess less confidence in their capability to perform a task. On the other hand, participants that set more challenging and meaningful goals for themselves are more likely to exert additional effort in order to achieve increased performance than those that set less challenging objectives for themselves. In order to account for other pre-training differences, the authors also included prior experience and age as determinants of computer task performance. Results from their structural model showed no significant direct effect of CSE on performance, but did show a significant, if rather small, indirect effect through personal goals. Prior experience had a strong positive effect and age a negative one on performance. Overall, the model proposed by Yi and Im (2004) accounted for almost 40% of the variance in the dependent variable.

Also within a training context, Johnson (2005) proposed two mediators, in addition to a direct effect, of the relationship between application-specific self-efficacy and performance: goal level and goal commitment. These two mechanisms have been shown to be primary determinants of the motivation with which individuals approach tasks and improve performance. Individuals who set challenging goals for themselves exert greater effort and maintain it for longer, and perform better than those who set lower goals. Commitment to these goals, however, is required for them to have any motivational impact on performance; personally, meaningless objectives are unlikely to motivate greater effort expenditure.

Indeed, these motivational processes have been shown to be two of the primary channels by which cognitive appraisals of capability (e.g., efficacy beliefs) operate on behavior and ultimately performance in the series of studies by Bandura and colleagues (Bandura and Jourden, 1991; Bandura and Wood, 1989; Cervone et al., 1991; Wood and Bandura, 1989a). Results from Johnson (2005) confirm these previous findings. Application-specific CSE has significant impacts on performance both directly and through its positive effects on self-set goals and goal commitment, for a combined standardized path coefficient of 0.2933. In addition, it explains 13% and 14% of the variance, respectively, in the two mediating constructs.

Marakas et al. (2007), although specifying CSE as a formative composite, also examined its relationship to performance in the context of analyzing the differential predictive validity of measures developed at different points in the evolution of the computing domain. In order to accomplish this, the authors compared the spreadsheet measure used by Gist et al. (1989) and the one developed by Johnson and Marakas (2000). While both measures significantly predicted spreadsheet performance, the more recent essentially tripled the proportion of variance explained in the dependent variable (it is not clear whether the scale developed by Gist et al., 1989, was also specified as a formative composite).

39.5 CSE and Technology Adoption

In addition to performance, researchers also investigated the role of CSE as a distal predictor of technology adoption behavior and as an antecedent to perceived ease of use (EOU). Although Davis (1989) originally considered self-efficacy as part of the root formulation of perceived EOU, later research positioned CSE in its current role. Venkatesh and Davis (1996) conducted a three-experiment study to test, among other relationships, the hypotheses that GCSE would be a strong predictor of perceived EOU, both before and after hands-on experience with the focal systems. Results from this research revealed significant and large effects of CSE on perceived EOU, both for two different systems and before and after hands-on use. The authors theorized, and empirically supported, that objective usability of the application would only be a factor after participants in their studies had the opportunity to experience the systems by themselves, but that in either case, subjects would still anchor their general perception of EOU on their individual level of self-efficacy.

Building on these results, Venkatesh (2000) used an anchoring and adjustment framework to propose that in forming system-specific EOU, individuals anchor on key individual and situational variables

that relate to control, intrinsic motivation, and emotion. With increasing experience, individuals adjust their system-specific perceived EOU to reflect their interaction with the system. Understanding determinants of EOU, such as CSE and computer anxiety, become important from two standpoints: (1) the construct has a direct effect on intention to adopt and indirectly through perceived usefulness and (2) perceived EOU is argued to be an initial hurdle that users have to overcome for acceptance, adoption, and usage of a system. In the absence of direct hands-on experience with new systems, perceived EOU of systems is not distinct across different new systems, suggesting the existence of "common" set of determinants. In this light, CSE and computer anxiety are conceptualized as anchors of this perception. Through a multisite longitudinal (three measurement points) study, the author showed the consistent and strong effects of both constructs on perceived EOU, which did not significantly change as additional experience with the application was gained.

Agarwal et al. (2000) also examined the relationship between CSE and perceived EOU, but distinguished between general and specific levels of the former. In this research, both perceptions of efficacy and EOU were conceptualized at the level of particular applications: the general Windows environment and a spreadsheet package. In addition, a general measure of CSE, adapted from Compeau and Higgins (1995b), was used. The authors predicted that the specific self-efficacy measure would be a more proximal predictor of perceptions of EOU, given that it was a particularized judgment, as opposed to the more global feeling of confidence represented by the more general measure of computer efficacy. Their results show the specific efficacy measures having significant effects on their respective EOU judgments, and the more general measure having indirect and partially mediated direct effects on perceived EOU for Windows (through the specific Windows self-efficacy measure).

CSE was also included as part of the nomological network of the construct of cognitive absorption, developed and validated by Agarwal and Karahanna (2000). Cognitive absorption, defined by the authors as a "state of deep involvement with the software" (p. 673) was tested in relation to the two main technology acceptance beliefs, perceived usefulness and perceived EOU (Davis, 1989). The inclusion of CSE as an antecedent to these beliefs served to help establish the value of the new construct over and above already known influences. In addition to this purpose, beliefs of efficacy were found to have a significant and positive effect on perceived EOU, once more validating the important role CSE has on forming these perceptions and, by extension, in the overall process of technology adoption.

39.6 Impact on Practice

The study of both CSE and GCSE has had a significant impact on both the applied and academic communities. Given its known relationship to performance, the applied community has a powerful tool to effect improvements to computer-related task performance throughout its workforce.

The distinction between internal and external sources of efficacy was first formulated by Eden (2001) based on earlier work on Pygmalion-style leadership (Eden, 1988, 1990, 1992), conceptual distinctions between different sources of efficacy beliefs by Gist and Mitchell (1992), and earlier work on the subjective assessment of the adequacy of tools for job performance (Eden and Aviram, 1993). Though of relatively recent appearance in the management literature, there is a small but growing collection of empirical studies that provides support for the validity of its main propositions across a number of different contexts, such as *psychology* (Stirin et al., 2011), leadership (Walumbwa et al., 2008), *training* (Eden and Sulimani, 2002), and, most notably, *the introduction of new information technologies to the workplace* (Aguirre-Urreta, 2008; Eden et al., 2010).

The vast majority of research related to self-efficacy, however, has been conducted following the seminal work of Bandura (1986b, 1997) with its clear focus on self-efficacy as a subjective judgment of competence for performing specific actions or achieving specific goals. Indeed, Bandura (1997, p. 21) defines self-efficacy as "… a judgment of one's ability to organize and execute given types of performances." After more than 30 years of research in this area, there is overwhelming empirical evidence of the effects of self-efficacy on performance, in both the psychology and management literatures, which includes

experimental evidence in both laboratory studies and field experiments (Bandura and Jourden, 1991; Bandura and Wood, 1989), that support the causality of those relationships. There is also ample literature on the determinants of self-efficacy (Bandura, 1997; Gist, 1989; Gist and Mitchell, 1992).

39.7 Implications for Future Research into CSE and GCSE

As discussed in the opening comments of this chapter, it may be easy to conclude that the pervasive nature of computing technologies and their associated skills has rendered further investigation in CSE a moot issue. We wish to be clear that we believe nothing could be further from the truth. As computing technologies continue to become a part of our daily lives, any research that advances our understanding with regard to how we mere mortals interact and perceive such technologies must be regarded as relevant. To that end, continued research focusing on the CSE construct at all levels of analysis and all generalizable contexts should be encouraged and welcomed by both the academic and applied communities alike.

Despite the rich empirical literature, across a wide variety of disciplines, into the CSE construct, there exists a significant portion of our body of knowledge in this area yet to be determined and validated. Extant research has largely ignored the temporal development of self-efficacy beliefs and the possibility of different individual patterns underlying their growth. While this is a rather common limitation of this literature, which has largely focused on cross-sectional and between-individual studies, rather than considering intra-individual variation, a wide variety of specific areas of focus and specific research questions remain to be addressed and answered. Future research should study whether the development of the self-efficacy construct occurs at different rates for different individuals. Further, is there a ceiling effect with regard to either the development of CSE perceptions or their effects on performance-related constructs? Such research becomes important as we begin to place greater emphasis on the development of computer literacy at the elementary education levels. Is there an optimal starting point for such skill development as it relates to raising levels of CSE or GCSE? Can we manipulate CSE at early stages of chronological and cognitive development to mitigate the known gender bias observed in much of the CSE research? Can we use the temporal development of CSE in individuals to predict future performance in computer-related domains? The answers to such research questions would serve to inform for the applied and academic communities and would become instrumental in the design and development of more rigorous and complex training programs and mechanisms.

Along these same lines, research should focus on whether these individual temporal patterns of growth and development of CSE beliefs can be reduced to a limited number of archetypes and can be, therefore, identified based on observable features such that targeted development interventions can be derived. This line of research would be of value not only to the information systems domain, but also to the general literature on efficacy beliefs and human development, and falls in line with recent calls to reconsider the importance of individual units of analysis in psychology (Molenaar, 2004).

Another fruitful area of research that has remained largely unexplored is the determination of exactly what the relationship is between the task-specific CSE and the GCSE level. Marakas et al. (1998) theorized a relationship between the two levels similar to that depicted previously in Figure 39.2. Despite this conceptualization rapidly approaching two decades old (along with the popular application of the GCSE construct in numerous research efforts), no known empirical work has been conducted to validate this conceptualization—or any other, for that matter. It seems reasonable to conclude that the level of interest with regard to the use of the two levels of the construct can be advanced only by an empirical investigation into their true relationship to each other. Is GCSE simply a weighted average of the sum of CSE formations as suggested by Marakas et al. (1998) or is there a different mechanism in place? Do all CSE formations contribute to a formation of perception regarding GCSE or is there a point where no further significant change in GCSE levels is observed despite continued exposure to new opportunities to form CSE perceptions at the task-specific level?

More recently, work by Marakas et al. (2007) specified CSE using a formative, as opposed to reflective model. Up to this point, researchers using SCT, and even within the domain of computing, had always

used the latter form to posit the relationships between latent and manifest variables. The authors argued for this new conceptualization of CSE by noting that indicators currently used to measure the construct did not necessarily follow any particular pattern of correlations, as required by the reflective mode of measurement. In particular, they proposed that a person answering positively to one item might not necessarily answer in a similar manner to a second one, e.g., "It is possible, even likely in many cases, a person responding to the instrument might be capable of installing software, but not capable of accurately describing how a computer works" (p. 21).

The road chosen by Marakas et al. (2007) follows a literature that has so far been mainly concerned with the issue of direction of causality between manifest and latent variables (Bollen and Lennox, 1991; Edwards and Bagozzi, 2000; Jarvis et al., 2003; Mackenzie et al., 2005). As argued by Diamantopoulos and Siguaw (2006), it is not clear why researchers seem to argue that, following a process of measurement construction, the same items should have been selected to comprise either formative or reflective specifications. Pushing the issue a little further, it is also not clear why Diamantopoulos and Siguaw (2006) believe that the issue boils down to selecting different items from the same pool, as opposed to creating separate pools of items altogether. In all this literature, however, there is a more fundamental question that has so far been left unanswered, and from which all other considerations follow directly, namely, why would a researcher choose a reflective or formative specification in the first place? Borsboom et al. (2003) propose that the answer depends on the ontological status of the latent variable being invoked in the research model. In addition, a number of other important issues arise from the choice of specification that extends beyond the mere direction of arrows in the graphical depiction of a causal model, such as the error-free nature of the manifest indicators. Recent research has also questioned the quantitative accuracy of studies implying that misspecification of formative specifications as reflective result in large estimation biases (Aguirre-Urreta and Marakas, 2012), and even others disagree with the choice of model specification by Marakas et al. (2007), as well (Hardin et al., 2008a,b). While the issue of model specification has implications that extend beyond the CSE construct, it has happened that this construct has become the subject matter on which many of these issues are discussed.

This area of focus, along with those previously identified, provides a rich and fertile opportunity for CSE research. Beyond the work conducted by Marakas et al. (2007), no specific focus on advancing our understanding of this debate has been identified. Future research should begin an organized effort to better understand the implications of specifying the construct as formative or reflective. Is it possible that each perspective provides a window into a better understanding of the construct or its direct implications to the applied community that the other does not? Can the two perspectives be reconciled such that the decision as to how to specify the construct lies with the convenience of the researcher? Does the level of analysis at which an investigation is conducted receive any benefit from one perspective over the other? The benefits derived from this area of future research will most assuredly extend beyond the CSE research community and, as such, potentially provide a much larger return, as measured by the breadth and depth of potential beneficiaries, than those discussed earlier. Regardless of the chosen area of focus, however, the need for continued and varietal research into the CSE construct appears to be both clear and unequivocal. Any thought of the sun setting on this stream of research is still far off in the distance, to be sure.

39.8 Summary

The CSE construct, and its related general level, has enjoyed, and continues to enjoy, a rich nomological net developed from a wide variety of disciplines and empirical studies. Further, it stands as one of the few academic foci that can be easily extended into the applied realm to effect material changes and value with regard to the continued development of computer-related skill sets.

Given its strong theoretical foundation, CSE represents a product developed within the academic realm, through the combined efforts of a wide variety of researchers, that has sustainable value in furthering our understanding of human behavior in a society where computing technologies are, and will continue to remain, pervasive.

Developing Individual Computing Capabilities

Saurabh Gupta
University of North Florida

40.1 Introduction

Individual computing capabilities development continues to be a rich area of investment for enhancing the productivity of individuals, with over 38% of all training directed toward IT training (ASTD 2008). With an increasing percentage of both large and small businesses using computer applications in their daily work, this trend is likely to continue. Recent surveys have found that computer literacy requirements have skyrocketed in almost every job category. For example, over 70% of the companies included in the previous referenced survey now require computer competency in their middle and senior management positions. In addition, research has also shown that development of computing capabilities has a significant effect on new technology adoption (Igbaria et al. 1995).

Considerable amount of research has been done investigating methods to develop individual computing capabilities over the years. Early research in this area focused on traditional training methods in a structured classroom environment. However, an increase in the requirements for continuous learning and growth in the geographic dispersion of trainees is creating a "demand-pull" for going beyond the classroom-based training methods. This, combined with the declining cost of hardware and increasing ubiquity of communication networks, is creating an incentive for many organizations to move toward technology-mediated training or e-learning.

Over the years, three critical frameworks have been proposed to explain the development of individual computing capabilities (Alavi and Leidner 2001; Gupta and Bostrom 2009; Olfman and Pitsatron 2000). These frameworks, however, do not provide a consistent picture of the computer training phenomenon. While two of these focus on the psychological process of learning (Alavi and Leidner 2001; Olfman and Pitsatron 2000), they ignore the role of technology-mediated learning as well as the role of individual interaction with the training method. On the other hand, the most recent framework ignores the psychological learning process, focusing instead on the role of learning systems and their interaction with the learners (Gupta and Bostrom 2009).

The goal of this chapter is to define the nature of individual computing capabilities, outline the key underlying principles based on an integrative framework, along with their practical implications, and identify key areas of future research.

40.2 Defining Individual Computing Capabilities

Individual computing capabilities represent an understanding of the principles by which a system can be applied to a business task (Garud 1997). Drawing from research in educational psychology and IS, individual computing capabilities can be classified into four categories: skill-based capabilities, cognitive capabilities, affective capabilities, and metacognitive capabilities (Gupta et al. 2010).

Skill-based capabilities focus on the ability to use the target system. It is based on two specific types of knowledge base: command-based and tool procedural knowledge. Command-based knowledge is the knowledge of the syntax (set of commands and the command structure) and semantics (meaning of the commands) of the target system. Tool procedural refers to grouping these individual commands to perform a function or task. Without this level of knowledge, users are unable to use the system or recover from errors.

Cognitive capabilities focus on the mental awareness and judgment of the user. Business procedural, tool conceptual, and business conceptual knowledge bases focus on cognitive capabilities. Business procedural or task-based knowledge is about applying tool procedures to business processes. Tool conceptual knowledge focuses on the big picture, that is, the overall purpose and structure of the target system. Acting as an advance organizer, this knowledge provides a basis for the ability to transfer learning to new situations. Business conceptual is the knowledge of the specific business processes supported or enabled by the target system. This knowledge is required to understand the interdependencies of actions in complex systems.

Affective capabilities focus on the emotional aspects of the user's behavior. A review of the literature shows that three affective capabilities have been analyzed in IT training area (Gupta et al. 2010). The first one, motivational knowledge, is the knowledge about what the target system can do for the user's job, the organization, etc., that is, the usefulness of the software to the organization. The second important affective outcome is satisfaction with the training process. Given the continuous need for training, training programs are designed to not only impart knowledge, but also provide a high level of satisfaction. The last affective learning outcome, perceived anxiety, has received much less attention in IS research. Perceived anxiety deals with a feeling of apprehension, tension, or uneasiness in the capabilities of using the target system.

Metacognitive or self-regulated learning knowledge refers to an individual's knowledge regarding their own learning and information-processing processes. Among the most commonly investigated metacognitive variables is self-efficacy or users' belief about their ability to perform a specific behavior (Bandura 1986). Self-efficacy has been shown to affect other training capabilities and to be a strong antecedent to post-training intention to use (Compeau et al. 2005).

40.3 Underlying Principles for Individual Computing Capability Development

As mentioned earlier, two distinct research perspectives have been proposed to explain the development of individual computing capabilities, especially for the contemporary environment. The first one, characterized by Alavi and Leidner (2001), models the impact of training method on training outcomes as mediated by the individual's psychological processes. It argues for a shift in our attention to understanding the relevant instructional, psychological, and environmental factors that enhance learning. The other model, by Gupta and Bostrom (2009), uses adaptive structuration theory (AST) as a basis. AST argues that the influence of these advanced information technologies is moderated by the actions of the actors (learners in this case) (Barley 1986; DeSanctis and Jackson 1994; DeSanctis

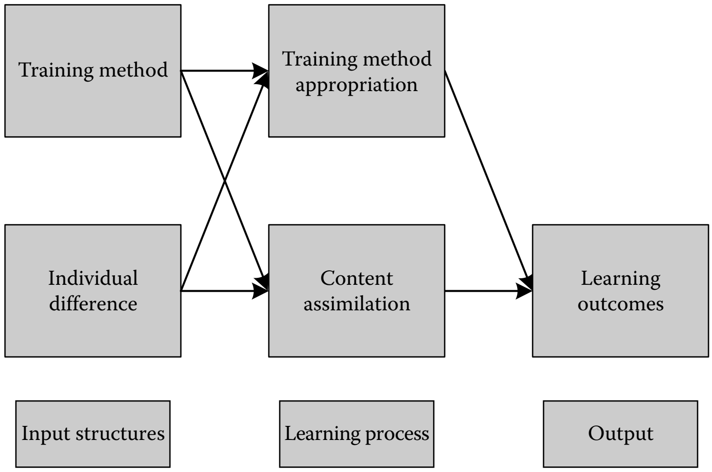

FIGURE 40.1 Individual computing capabilities development model.

and Poole 1994; Orlikowski 2000). AST makes both technology and human agents part of the system, accounting for the interplay between people and technology, as well as the full predictability of IS use in individuals, groups, and organizations (Fulk 1993). This allows AST to preserve the predictive potential of a deterministic perspective, while accounting for interpretive flexibility of the process perspective (Gouran 1989). Researchers have also argued that AST presents a good metatheory for IS research (Bostrom et al. 2009).

Using this as a basis, the model outlined by Gupta and Bostrom (2009) outlines the impact of training methods on training outcomes as moderated by the faithfulness of appropriation of training methods. These seemingly inconsistent models have one thing in common. Both stress the importance of learning process as well as the importance of individual differences. However, these models focus on different aspects of the learning process.

The model outlined in this chapter (see Figure 40.1) integrates the two models to provide a comprehensive overview of the development of individual computing capabilities through training. The combined model highlights five distinct constructs: training methods and individual differences as inputs into a training situation, appropriation of the training method and the psychological process as a part of the learning process, and the training outcomes as the final construct. The input structures and learning process are discussed in the following sections. We have already discussed individual computing capabilities earlier.

40.3.1 Input Structures

Training situations involve two critical inputs. The first one is the training method, as designed by the trainer, and the second is the individual trainees themselves. From an AST perspective, these are considered as input structures into a process.

40.3.1.1 Training Methods

A training method is defined as a combination of structures that guides individuals to achieve the learning outcomes. DeSanctis and Poole (1994) state that input structures can be described in terms of their features and spirit.

The spirit of a training method can be described in terms of the epistemological perspective the training method follows. Epistemology describes overarching beliefs about the nature of knowledge and about what it means to know something (Hannafin et al. 2004). It provides a design template for creating process and content structures embedded in the learning method. We utilize the most

TABLE 40.1 Epistemological Perspectives

Epistemological Perspectives	Assumption about the State of Knowledge	Learning Outcomes Focus On	Learning Happens By	Traditional Learning Technique	Technology-Based Learning Technique
Behaviorism	Objective	Conditioning learner behavior	Response to stimulus	Direct instruction	Drill
Cognitivism	Objective within context	The learner's thought process	Acquiring and reorganizing the cognitive structures	Behavioral modeling	Intelligent tutor
Constructivism	Constructed reality	The learner's ability to construct reality	Constructing new ideas or concepts based on prior knowledge and/or experience	Unguided case study	Self-regulated
Situationalism	Negotiated reality	Social construction by the learner	Participate and behave as a member of the community	Discussing, writing	Computer supported collaborative learning (CSCL)

common classifications in both IS and education literatures: behaviorism, cognitivism, constructivism, and situationalism (Leidner and Jarvenpaa 1995; Vries 2003). Table 40.1 describes these perspectives, their underlying assumptions, traditional learning techniques, and technology-based technique used to operationalize these perspectives.

The behaviorist view is based on the assumption that human behavior is predictable. Under this theory, learning takes place when new behaviors or changes in behaviors occur as the result of an individual's response to stimuli. Thus, the end goal is defined upfront, and each step necessary to achieve the goal is given to the learners (Burton et al. 2001). For example, direct instruction, which is the most popular form of learning method, is based on this perspective.

The cognitivist perspective holds that learning is a process that is dictated by the participant's cognitive structure and the presentation of the information to the participant. Under this perspective, learning is the change in the mental model as a result of the training. Thus, training methods under this theory have a predefined goal along with information necessary to reach the goal, but the process of cognition of the information is left to the learners (Winn and Snyder 2001). Several researchers have also compared training methods based on behaviorist and cognitive perspectives (Carroll et al. 1997; Olfman and Mandviwalla 1994; Santhanam and Sein 1994), as well as conceptual model or procedural model (Mayer 1981). Sein et al. (1989) found that the effectiveness of the conceptual model depends on the individual user characteristics interacting with the conceptual model and not on the type of model alone. More recently, Coulson et al. (2003) investigated the effectiveness of conceptual models for complex systems. When controlling for initial knowledge, the research found a significant positive effect for using a conceptual model.

The most prevalent theory used to understand participant learning in education as well as in IS is Social Cognitive Theory (Bandura 1986). This theory states that it is not just the exposure to a behavior, but learner action in exploring, manipulating, and influencing the environment that counts. Two kinds of observational learning methods have been differentiated in theory: (1) observation of others' actions, referred to as vicarious learning/modeling or behavior modeling and (2) observation of self-actions or enactive learning (Schunk 2004). Much of the end user training (EUT) literature has focused on vicarious modeling (VM) as a method of learning. Table 40.2 summarizes the literature in this area. Vicarious modeling treatment in previous research has been done by using an external actor to demonstrate actions (usually packaged in a video). Instructor-based treatment, on the other hand, uses the same content, but without demonstrations of the content being taught. A consistent finding is that VM yields better training outcomes than other methods such as instructor-based instruction or studying

TABLE 40.2 Vicarious Learning Literature in IT Training

Study/Target System	Training Intervention	Learning Outcomes	Findings
Gist (1988): Spreadsheet	VM vs. instruction-based training	Skill: Task performance	VM yielded higher task performance scores for both younger and older trainees
Compeau et al. (1995): Lotus 1-2-3 & WordPerfect	VM vs. instruction-based training	Skill: Task performance Metacognitive: Computer self-efficacy (CSE)	Subjects in the VM condition developed higher CSE and performed better than those in the instruction-based condition for spreadsheet program, but not for a word-processing program
Simon et al. (1996): MicroSnap II	Instruction exploration and VM	Skill: Task performance Cognitive: Comprehension Affective: End user satisfaction	VM outperformed the other two methods on all learning outcome measures
Johnson et al. (2000): Excel	Modeling vs. instruction-based training	Skill: Task performance Affective: Computer anxiety Metacognitive: CSE	Subjects in modeling treatment developed higher CSE and performed better than those in nonmodeling treatment. Computer anxiety was significantly related to CSE and task performance.
Bolt et al. (2001): Word and Excel	VM vs. instruction-based training when controlling for complexity	Skill: Task performance Metacognitive: CSE	VM outperformed nonmodeling when complexity was high
Yi et al. (2001): Excel	VM with practice vs. VM with retention enhancement vs. VM with retention enhancement and practice	Skill: Task performance Affective: Attitude	Subjects in the VM with retention enhancement and practice showed higher levels of learning outcomes when compared to the other groups
Yi et al. (2003): Excel	VM vs. VM with retention enhancement	Skill: Task performance Cognitive: Declarative knowledge Metacognitive: Self-efficacy	Subjects in the VM with retention enhancement showed higher levels of learning outcomes
Davis et al. (2004): Excel	VM vs. VM with symbolic mental rehearsal (SMR)	Skill: Task performance Cognitive: Declarative knowledge	VM with SMR was better than VM alone. Learning outcomes were mediated by the trainees' knowledge structures
Gupta (2006): Excel	VM with practice vs. VM with enactive learning (e-learning) vs. Collaborative learning in both treatments	Skill: Procedural knowledge Cognitive: Declarative knowledge Metacognitive: Self-efficacy, specific self-efficacy, satisfaction	Overall, VM with enactive learning performed better. The learning process was mediated by the attitude toward e-learning technology

from a manual. Current research has also tested four enhancements to VM: practice (Yi and Davis 2001), retention enhancement (Yi and Davis 2003), symbolic mental rehearsal (Davis and Yi 2004), and enactive learning (Gupta 2006). No significant impact of practice was found, but the later three enhancements have had a significant impact on learning outcomes.

The third perspective is the constructivist perspective, which states that individuals construct knowledge by working to solve realistic problems. Under this perspective, learning is the process whereby individuals construct new ideas or concepts based on prior knowledge and/or experience. A constructivist

designer usually provides all the information necessary for learning, but allows the learner to absorb the materials and information in a way that is most comfortable and to arrive at their own conclusions (Duffy et al. 2001). Self-regulated learning to develop individual capabilities is an example of such a perspective; in recent studies, it has shown promise (Gravill and Compeau 2003; Kadlec 2008).

The situationist perspective on learning highlights the fact that meaning is not bound to the individual. Instead, meaning is socially constructed through negotiations among past and present members of the community involved in the domain. According to the proponents of this perspective, authentic activities, that is, the ordinary practices of the domain culture rather than traditional classroom activities, are needed for knowledge to be constructed. Computer-supported collaborative learning is a prime example of learning using this perspective. Drawing from the theory of personal relevance, Ross (1983) argued that motivation is enhanced in settings where personally relevant information can be processed and there exists a direct involvement in the message being evaluated. Olfman et al. (1991) compared training methods organized as application-based (personally relevant) or construct-based and found no significant difference in training outcomes, though there was some evidence that application-based training is best for novice users. Kang et al. (2003), investigating a similar phenomenon, suggested that training should include a broader context knowledge to be successful.

In summary, the most examined training methods in IT training are based on social cognitive theory. These methods, in general, have proven to be significantly better than traditional lectures. However, specific benefits have also been shown using training methods based on other epistemological perspectives. Thus, an important research theme would be to investigate what combination of epistemological perspectives, for example, combining demonstration within a specific situation, should be adopted in a given context: target system, individual differences, etc. In addition, how contemporary instructional technology can be incorporated in training continues to be a challenge. With the increase in the number of structures available for IT training like collaboration, learning objects, simulations, etc., there is also need for a good contingency theory in this area. Practitioners are struggling with how to create blended training methods. Systems design research (Schonberger 1980; Zhu 2002) and summary of various conceptualizations of fit (Venkatraman 1989) present a good foundation for a research stream in this area. Alternatively, design theories have argued for a theory-based design of training programs (Hevner et al. 2004; Reeves et al. 2004). Both of these areas present a very promising stream of research that will help explain inconsistent previous results, filling an important gap in the current body of knowledge.

40.3.2 Individual Structures

Individual differences have played an important role in IS (Sun and Zang 2005) as well as in education research (Lehtinen et al. 2001). In education, individual difference variables define the cognitive aspects of human activities that are often referred to as "learning ability." These variables influence training outcomes directly, by forming mental models, or indirectly, through interactions with training methods (Olfman and Pitsatron 2000). Table 40.3 summarizes the previous research with respect to these variables.

Generally, individual difference constructs are classified as traits or states (Bostrom et al. 1990). A trait is a distinguishing feature of an individual's nature and is relatively enduring, while psychological states are general emotion-based characteristics relating to the current context. States are dynamic; they change over time and from one situation to another.

The most examined individual differences are self-efficacy, motivation, and learning styles (see Table 40.3). More generally, in the case of both states and traits, IT training researchers have found a strong impact of individual differences on capability development. Theoretically, most IT training has focused on the direct impact of individual differences on individual capability development. This is consistent with the lower half of the model presented in Figure 40.1. The model states that individual differences affect the psychological process of content assimilation directly, which, in turn, affects learning.

TABLE 40.3 Individual Differences Research in IT Training

Study/Target System	Individual Difference	Learning Outcomes	Findings
Traits			
Sein et al. (1989); Bostrom et al. (1990): E-mail Sein et al. (1991): Email & Lotus 123 Bohlen et al. (1997): Word-processing	Kolb learning style	Skill: Near transfer tests, far-transfer tests, efficiency Affective: Satisfaction	Abstract modelers performed better than concrete modeling subjects, especially in far-transfer tasks. Assimilators did not show a significant difference in learning outcomes between computer-based training (CBT) and lecture-based training.
Gist (1988): Spreadsheet Webster et al. (1993): WordPerfect	Age	Skill: Test performance Affective: Post-training motivation to learn	Younger trainees performed better. Task labeling as play is better than task labeling as work for younger participants, but this was not true for older participants.
States			
Compeau et al. (1995): Lotus 123, WordPerfect Johnson et al. (2000); Marakas et al. (1998): Excel Martocchio et al. (1997): Windows 3.1	Self-efficacy	Skill: Task performance Metacognitive: Computer self-efficacy	Pretraining self-efficacy significantly influenced post-training learning outcomes.
Szajna et al. (1995): Basic IT skills	Computing attitude and achievement	Skill: Learning performance	Computing attitude and achievement are related to performance.
Szajna et al. (1995); Keller et al. (1995): Basic IT skills	Anxiety	Skill: Learning performance	Anxiety was not related to learning performance. Anxiety has significant interaction with training method.
Yi et al. (2003): Excel	Intrinsic motivation	Skill: Task performance Cognitive: Declarative knowledge Metacognitive: Self-efficacy	Positive correlation between intrinsic motivation and learning outcome.
Gravill (2004): Oracle 11i Navigator	Metacognitive + Self-regulated learning strategies + Goal orientation + Self-awareness + Task attention	Skill: Procedural knowledge Cognitive: Declarative knowledge Metacognitive: Self-efficacy	Learners who devoted effort toward the use of self-regulated learning strategies benefited in terms of higher learning outcomes.

Since, in most cases learning outcomes are used as a proxy for measuring content assimilation, it explains the direct effect that most of these studies found.

On the other hand, research in educational psychology (classified as aptitude treatment interaction) suggests that an individual's aptitude has an interaction effect with learning methods on learning outcomes (Ackerman et al. 1999). However, education researchers also noted that much of the learning process research has focused on post hoc analysis of results or on opinions of the researcher rather than theory-driven empirical analysis (Rohrbeck et al. 2003). In IT training literature, Szajna et al. (1995) found that computing aptitude and achievement are related to learning performance, whereas anxiety and preexisting experience are not. However, Khalifa et al. (1995) found a significant interaction effect for anxiety; students with higher initial anxiety did significantly better in a more supportive environment. Theoretically, this can be explained by the fact that individual differences have a direct impact on how a person appropriates the learning method, which in turn has an effect on individual capability development. However, in spite of the aforementioned theoretical arguments, the impact of individual differences on appropriation of training method has not been investigated in the IT training literature.

Overall, more work is needed in this area to clarify the role of individual differences in developing individual computing capabilities. In this regard, more IT-specific traits and states need to be examined further. In a learner-centric era, where the learner is responsible for learning, the impact of these IT-specific traits and states is likely to grow and create significant challenges needing further investigation (Salas and Cannon-Bowers 2001). For example, one salient trait found to apply in other IS contexts, yet not examined in EUT research, is personal innovativeness in IT (Agarwal and Karahanna 2000). In addition, researchers focusing on individual differences should examine both the direct effects on learning outcomes and the effect of individual differences on learning process. The model and arguments presented earlier provide a good framework for researchers to examine the effect of individual differences and assertions stated previously.

40.3.3 Process Mechanisms

The learning process is a series of actions or cognitive development that leads to a change in an individual's capability. Two critical activities happen during this process. First is the interaction of the individual with the elements of the training environment, and second is the development of mental models. Both are discussed later.

40.3.3.1 Structural Appropriation

The model outlined in Figure 40.1 provides AST as a basis for measuring the learning process. The learning process is viewed as an appropriation or structuration process where participants learn and adapt the learning method structures based on their interpretation of the designer's intent. Like all perceptions, this interpretation varies among learners. Although educational researchers do not have a concept similar to appropriation, they have focused a lot on scaffolding because of its importance (Chang et al. 2009; Ge and Land 2003). Scaffolding presupposes appropriation of structures/learning methods but focuses on how to guide or facilitate appropriation instead of structural impacts. The concepts of scaffolding and appropriation complement each other and would be useful for investigating use of learning method structures.

Assuming that the learning method reflects the values and assumptions of the epistemological perspective and the learning capabilities (i.e., for well-designed structures), a faithful appropriation occurs when participants' interaction is consistent with the spirit (Poole and DeSanctis 1992). Faithfulness is not necessarily concerned with the precise duplication of the procedures provided; rather, it is concerned with whether the structures are used in a manner consistent with the overarching intention in which the designer intended the system to be used. A participant's unique or innovative use of the structures may well be a faithful appropriation as long as their use is consistent with the spirit that the learning method intended to promote (Chin et al. 1997). Ironic appropriation occurs when the participants' interactions violate the spirit of the structure with or without abandoning the underlying learning method (Poole and DeSanctis 1990). In the case of well-designed learning methods, ironic appropriation could introduce internal contradictions within the structures governing interaction. Over time, these contradictions will cause tensions in interactions, which might lead to lower effectiveness of the structures. These contradictions must be addressed, detracting the participant(s) from the learning focus, leading to lower learning outcomes.

When analyzing technology appropriation, Poole and DeSanctis (1990) suggest three dimensions that indicate appropriation: faithfulness, attitudes, and level of consensus. That is, structures will only have their intended effect if the design principles are kept intact (faithfulness), if members do not react negatively to it (attitudes), and if members agree substantially over how structures are used (consensus). Considerable support for the proposition exists in AST literature, particularly the group support systems literature. Indirect support exists in the education literature, especially in the scaffolding literature. Most recently, in a follow-up to their conceptual model, Gupta and his colleagues studied appropriation as an influence on learning outcomes and found strong support (Gupta 2008).

40.3.3.2 Psychological Processes

The Alavi and Leidner (2001) model argues for a similar physiological or cognitive activity done by an individual as a part of the learning process. Their conceptualization of the learning process deals with how information is absorbed and stored in our minds, that is, content assimilation. Such a process deals with how a given content is captured to create new or modify existing mental models by the trainee. Analyzing the process, Davis and Yi (2004) found significant support for the importance of mental models on learning outcomes. Research in this area is often based on more general theories of content assimilation, such as Piaget's theory of cognitive development, Ausubel's theory of subsumption, or Mayer's theory of assimilation (Schunk 2004).

More specifically, educational psychologists have generally theorized three phases of learning: preparation for learning, acquisition and performance, and transfer of learning (Gagne 1985). Preparation for learning deals with the learners focusing on stimuli to the material and orienting themselves toward the goals. The main phase of learning is the acquisition and performance phase. This deals with recognizing the relevant stimulus features and transferring them to the working memory for processing. These are subsequently encoded, and new knowledge is transferred to create new/update existing mental models. Transfer of learning deals with developing models for new situations based on what has been learned. Only one study has examined this process in an IT training context (Yi and Davis 2003). This study, done in the context of social cognitive theory, found significant positive effect of the three aforementioned learning process phases on outcomes.

In addition to this, an individual can build a mental model of the system in three different ways: mapping via usage, mapping via analogy, and mapping via training. Only one research study on directly focusing on metal model building in an IT training context (focusing narrowly on mapping via training) has been conducted (Bostrom et al. 1990). While more studies are needed in understanding mapping via training, the other two methods also represent important areas in understanding how individuals build their computing capabilities.

In summary, the model in Figure 40.1 identifies four critical elements that influence the development of individual computing capability. The training methods, based on different epistemologies, and the trainees, with their individual differences, present the starting point. Individuals learn as they go through the process of content assimilation and training method appropriation. Key practical implications and future research areas are discussed next.

40.4 Practical Implications

The review of the literature presented in the previous paragraphs has many different implications in practice. First, individual capabilities need to be more broadly defined and assessed when compared to what has traditionally been done in practice. Most assessment methods focus only on skill-based capabilities, leaving out the other three. While skill-based capabilities are the foundation, the real exploitation of an information system is dependent on the levels of the other three capabilities.

Second, trainers need to shift their attention toward incorporating learning theories into their training methods. In addition, the literature clearly states that VM-based methods have the greatest impact on developing individual computing capabilities. Whether implemented in traditional environment or e-learning environment, trainers need to focus on how the components/features of the training method enhance critical dimensions of VM. Research also shows that certain enhancements, like the ability to take notes, work in simulations, work in teams, etc., can increase the effectiveness of VM.

The third implication deals with accommodating individual differences to personalized training. Personalization deals with the delivery of content that specifically meets the learner's needs and characteristics. Traditionally, the focus has been on the content of the training, and organizations have used job roles to define the content. However, with advances in technology, the focus is shifting to include the ability to personalize training methods using learning management systems (LMS). To personalize

the learning method, a learner profile that captures individual differences should be mapped to different learning methods. Next, LMS can be used to link these methods, preferences, and competencies as needed (Mayer et al. 2004). As such, profiling and job-role competencies categorizations need to be developed and investigated, especially before their use in LMS.

However, this result of good training method and personalization is contingent on the faithful use of e-learning technology by the users. Higher levels of appropriation, especially a positive attitude, toward new training methods, such as e-learning, have a substantial impact on the extent of learning. A practical implementation of this is to encourage participants to continue with e-learning solutions for a longer period, as experience helps in enhancing attitudes toward e-learning. More importantly, it shows the importance of developing a positive attitude upfront. Additionally, trainers should use scaffolds to enhance overall faithfulness of the learning method appropriation.

Overall, this chapter provides a comprehensive view of designing contemporary training programs, in classrooms, as well as virtually. These outcomes can be used not only by corporate businesses/consultants/trainers but also by instructors in K-12 and universities.

40.5 Key Research Issues

The model outlined in Figure 40.1 points to a broad gamut of potential research questions. Most of the research issues deal with the input structures and the learning process. Some of these issues, such as personalization, combination of training methods, changes because of emerging technology, etc., were mentioned earlier in the chapter. In this section, we focus on four important research streams that have not yet been mentioned.

Although not specifically highlighted in research models, the creation of input structures requires a lot of pretraining activities (Olfman and Pitsatron 2000). These activities not only influence the development and design of the training method, but the rest of the training process as well. The study of how these components influence the design and development of the training method thus represents an important research topic for the future. This research will also provide an important feed into the "personalization" aspect of training—a critical input area for the training industry.

From a learning process perspective, there are two distinct ways of investigating the appropriation of training methods. First is the structural focus, concentrating on how well the training method structures are appropriated by the learner. Gupta (2006) found support for the effect of faithfulness of appropriation on learning outcomes. An important implication of this is that future researchers need to account for the level of appropriation in the interpretation of their studies. The second way of understanding the learning process, and a more enduring research theme, is the process focus involving the microlevel analysis of the learning process and the reciprocal causation phenomenon. Very limited research has been done in understanding the "moves" trainees make as a part of the learning process. "Move" studies are usually done at a microlevel analysis of the appropriation process. Poole et al. (Poole and DeSanctis 1992) have identified nine categories of such moves and provide a good starting point for the analysis. Such a research stream would provide a significant contribution to understanding the adaptive structuration process from the trainee's perspective. In all of the previous cases, researchers have suggested that the influence of structures changes over time and thus argue for longitudinal studies (Davis and Yi 2004; Gupta 2006). However, very limited knowledge currently exists on how appropriation changes over time and the causes for the changes.

Additionally, the learning process can also be manipulated through appropriation support or scaffolding for the training. There are various forms of process appropriation (procedural, metacognition, and strategic) support that need to be further studied. Procedural scaffolding helps learners make navigation decisions, such as how to utilize available resources and tools. Metacognitive scaffolds support individual reflection on learning, such as soliciting estimates of current understanding or cuing participants to identify prior related experiences they can reference. Strategic scaffolds support learners in anticipating their interactions with the learning method, such as analyzing, planning, and making

tactical decisions. Different support forms are likely to have different influences on the learning process and would represent an important contribution to this stream of literature.

Finally, researchers also need to deal with the continuous and real-time nature of learning. Companies and vendors are incorporating learning technology into their applications and products. Given the nature of current technology evolution, IT training needs assessment will soon not be treated as a distinct event needing follow-up; rather, needs assessment using technology will be continuous, job-driven, and done on demand (Gruene 2005). In either case (whether needs assessment is done in real-time or not), an important research question is: How should organizations best assess the end user skill gap, especially using technology? In addition, as highlighted in the chapter, the capabilities of an EUT program are expanding. Different job roles using a variety of information systems need different kinds of knowledge (DeSousa 2004). Such a spread of information systems, coupled with the breadth of job roles associated with software, provides a compelling need for future study.

40.6 Concluding Remarks

Individual computing capabilities are very important productivity tools in today's digital economy. A particularly large number of job postings highlight this need. In this chapter, we have synthesized existing knowledge on the factors that could influence the development of individual computing capabilities, presented a nomological framework for organizing extant research, and provided areas of future research on ways to improve training effectiveness.

Glossary

Appropriation of learning method: Participants learn and adapt the learning method structures based on their interpretation of the designer's intent.

Collaborative learning: Groups of students work together in searching for understanding, meaning, solutions, or in creating a product.

Content assimilation: A process that deals with how a given content is captured to create new or modify existing mental models by the trainee.

E-collaboration technology: Technologies that offer a rich, shared, virtual workspace in which instructors and students can interact one-to-one, one-to-many, and many-to-many in order to learn together anytime and at any place.

Epistemological perspective or spirit: General intent with regard to values and goals underlying the choice of structure.

Individual computing capabilities: Individual computing capabilities represent an understanding of the principles by which a system can be applied to a business task.

IT training: IT training deals with the teaching of skills to effectively use computer applications to end users.

Learning method structures: Learning method structures are formal and informal procedures, techniques, skills, rules, and technologies embedded in a learning method, which organize and direct individual or group behavior.

Learning outcomes: Learning outcomes are the result of the learning process. These can be broadly classified into four dimensions, namely, skill, cognitive, affective, and metacognitive outcomes.

Learning process: A series of actions or cognitive development that leads to a change in an individual's capability.

Technology-mediated learning or e-learning: An environment in which the learner's interactions with learning materials, peers, and/or instructors are mediated through advanced information technology.

Training method: A training method is defined as a combination of structures that guides individuals to achieve the learning outcomes.

Role of Trust in the Design and Use of Information Technology and Information Systems

Xin Li
University of South Florida

41.1 Introduction

Trust research has its long history in sociology, psychology, and business fields (Barber, 1983; Lewis and Weigert, 1985; Doney and Cannon, 1997). Mayer et al. (1995) defined trust as "*the willingness of a party to be vulnerable to the actions of another party based on the expectation that the other will perform a particular action important to the trustor, irrespective of the ability to monitor or control that other party*" (p. 712). The two parties involved in the trust relationship could be individuals or groups, such as organizations. Numerical research have suggested that trust is a key to understanding social relationships, as well as people's attitude and behaviors in the circumstances that uncertainty and/or risks are perceived (Mayer et al., 1995; Doney and Cannon, 1997; McKnight et al., 1998).

In the recent decades, the concept of trust has been introduced to information systems (IS) research. Specific research topics span from interpersonal trust in technology-enabled or technology-mediated environments (e.g., trust relationships in a virtual team or between online customers and web vendors) (Jarvenpaa et al., 2000; Piccoli and Ives, 2003) to trust in technological artifacts (e.g., trust in an online recommendation agent [RA] or trust in an inter-organizational system) (Ratnasingam, 2005; Wang and Benbasat, 2005). Trust has been widely found to play a crucial role in shaping information technology (IT)-related attitude and intended behaviors (Gefen et al., 2003; McKnight et al., 2011), especially behaviors of adopting a new, innovative, and emerging IT artifact (Luo et al., 2010) and of continuously using an IT artifact (Gefen et al., 2003). Trust research in IS has its roots in the traditional trust theories. Due to the new contexts, it also has its unique characteristics that traditional trust research may not address. We will discuss next the challenges IS researchers in this field have experienced in developing their own theories and literatures.

One challenge was the debate on the viability of the notion of trust in technology—whether trust, which usually requires moral capability and volitional control, can be extended to technological artifacts? It is not natural to label a technology as "honest" or "caring of others." But IS trust researchers stand on the shoulders of theories of social responses toward computing (Reeves and Nass, 1996; Nass and Moon, 2000), which posit that people treat computers and computer-based technologies as social actors and apply social rules to them. Recent IS research (Li et al., 2012) suggested that there could be multiple trusting objects involved in an IT/IS context. The technological artifact usually provides the functionality and reliability to complete a task, while the human actors (e.g., sponsors, designers, or other users) behind the technology contribute the volitional factors to the task performance and outcomes. Therefore, it is viable for people to trust technological artifacts in the sense that it is a dimension of the overall trust in the IT/IS context. Trust in technology has distinct psychological underpinning from traditional trust dimensions (e.g., trust in person), and they are complementary to one another to form trust outcomes. Researchers should not isolate trust in technology in their studies. Instead, they need to bridge it with other trust dimensions in the given context for a complete trust investigation.

Then how should a trust investigation be conducted in IT/IS contexts? Specifically, what trusting objects should be considered? How do people form trust toward different objects? How do the trust dimensions interact? What are their relative impacts on the trust outcomes? Numerous researchers have attempted to address these questions. However, their studies have adopted distinct focuses and lenses and used different terminologies. Also, trust is longitudinal in nature, and it evolves gradually along with the development of the relationships. All these reasons make it difficult to compare and contrast the research findings. There is no platform to establish an overview of the existing trust research in IS, to cumulate the research findings and build up the theories, or to provide systematic implications to the practice.

This chapter tries to close this gap by providing an overarching framework of trust in IT/IS contexts. The framework integrates various trust constructs and concepts studied in previous research, including interpersonal trust, technology trust, trust levels, trust developing stages, trust antecedents, and trust outcomes. It provides a comprehensive model for IS researchers to develop trust theories and a systematic guide to examine the role of trust in the system-design and system-use practices.

41.2 Underlying Principles

41.2.1 Trust in IT/IS

Beyond examining traditional, interpersonal trust in technology-mediated relationships, increasing research attention has been focused on technology trust. Technology trust, or trust in technology, refers to *the extent to which one is willing to depend on a technology because of its desirable attributes in performing certain tasks* (Pavlou and Ratnasingam, 2003; McKnight, 2005). When computer-based technologies have been widely used to complete individual or organizational tasks that were previously performed by other people, trust in these technologies becomes a key to understanding users' attitude and behavior in the contexts.

The notion of technology trust was not well accepted at first, as the traditional concept of trust requires volitional control for both the trustor (the party who grants trust) and the trustee (the party who receives trust). Based on theories of social responses toward computing (Reeves and Nass, 1996; Nass and Moon, 2000), IS trust researchers argued that computer-based technologies employed to substitute human roles and labor in completing certain tasks are usually seen and treated as social actors (Wang and Benbasat, 2005; Li et al., 2008). In human–technology interaction, all essential trust elements defined in traditional research (Mayer et al., 1995; Wang and Emurian, 2005) exist, and they work in the same way they do in interpersonal interactions. When using the technology to carry out a task, users develop the *expectations* on the technology-use process and the outcomes. They perceive *risks* in the situation too (e.g., what if the technology does not perform its responsibilities or reach the users' expectations). With all these

considered, users make a trust decision—how much they are *willing to be vulnerable* to the technology. For example, to use an e-commerce system on a website for online shopping, customers would expect smooth, secure, and successful transactions, no less than what they would get at a brick-and-mortar storefront. Specifically, they would expect the e-commerce system to present rich and accurate product information, to process order placement with a few easy steps, and to provide customer services like gift wrapping, shipping choices, easy exchange and return, order tracking, etc. Customers are aware of the possibilities of delayed delivery, unsatisfactory products or privacy breaches. Based on their beliefs and expectations, they are, however, willing to give it a try. With all these elements working in a human–technology relationship, trust in technology is as viable as trust in a person.

As trust research in IS has its roots in the traditional trust literatures, some research has extended the traditional trust theories and models to operationalize technology trust. Specifically, trust in certain IT artifacts was measured using human-like attributes, including competence, benevolence, and integrity (Wang and Benbasat, 2005; Vance et al., 2008). This approach works fine when the technology of interest is more "human-like" (Tripp et al., 2011). For example, an online RA is usually seen as a "virtual advisor" that gives shopping recommendations to online customers, as a store assistant or a human expert would do. Thus, customers treat RA similarly to a human trustee (Wang and Benbasat, 2005). However, when it comes to a less human-like technology, or one that is not easy to personify (e.g., Microsoft Access [Tripp et al., 2011]), this operationalization method may not work well.

An information technology is usually a preprogrammed, intelligent tool that presents its unique characteristics in task performance. These technical characteristics may be more germane to make up the trustor's expectations of the IT artifacts in terms of task performance and outcomes. Prior studies have included various technical attributes in their trust models, such as site/system quality (McKnight et al., 2002; Vance et al., 2008), Technology Acceptance Model (TAM) attributes (i.e., perceived easy to use and perceived usefulness) (Gefen et al., 2003), and technical competence, reliability, and media understanding (Lee and Turban, 2001). In a recent study, McKnight et al. (2011) investigated technical trusting attributes in a more systematic way. They compared one's trusting beliefs in an IT artifact and those in a person. Similar to human trustees that are expected to do things in a competent way, technological trustees are expected to demonstrate needed functionality to complete a task. While IT artifacts cannot be benevolent and caring of the trustors, they are expected to provide effective help. Instead of having human integrity, a technical artifact can demonstrate its reliability and operate consistently. This study proposed and validated the approach of operationalizing trust in technology using three technical characteristics—functionality, helpfulness, and reliability. This approach does not include any volitional factors. But, without the conceptual difficulties of anthropomorphism, this approach may be easier to operate in most technology contexts.

Other studies have compared and contrasted the two operationalization approaches of technology trust. Tripp et al. (2011) measured technology trust using both human-like attributes and system-like (technical) attributes across three different technology contexts. They suggested that human-like trusting attributes (i.e., competence, benevolence, and integrity) had a strong influence on people's use of technologies with higher humanness (e.g., Facebook), while system-like trusting attributes (i.e., functionality, reliability, and helpfulness) were more strongly related to people's use of technologies with low humanness (e.g., Microsoft Access). However, there is not a clear definition of humanness or a standard criterion to categorize the humanness of a technology, which makes this suggestion less practical.

Given all this, what is the best approach to measure technology trust? In an IT/IS context, a specific IT artifact plays a critical role in completing certain tasks, but it never works alone. The task performance and outcomes are also affected by other factors. For example, the performance of an enterprise system is determined by both the technical attributes of the system and nontechnical factors, such as collaborative management, organizational support, system transition process, and user training and support. The social, environmental, and human factors should also be considered to form user trust toward technology use. Therefore, it should not be the question of whether volitional factors are required in technology trust, or whether we can ascribe volitional attributes to an IT artifact, but rather what role technology trust plays in building the associated trust outcomes in the context. In an IT/IS context, multiple trusting objects may

exist and play distinct roles in completing certain tasks. The technological objects usually provide their functionality and reliability to ensure the completion of the tasks, while the organizational or human objects may contribute the volitional factors that affect the task performance and the outcomes. All these trusting objects should be considered to constitute the overall trust needed in forming the outcome attitude and behaviors.

41.2.2 Technology Trust and Interpersonal Trust

Although technologies have been used in various situations to replace human labor or to mediate human relationships, they do not totally replace the human role in the relationships. Specific technology is designed and employed by human actors for certain purposes, and the performance and outcomes of the technology may vary depending on the users and the procedures to use it. In order to use a technology, users need to trust both the technology and the human actors who exert impacts on the technology use. In contrary to technology trust, we call trust in the human actors as interpersonal trust. Li et al.'s (2012) study found that even in a pure e-commerce business where there is no physical storefront and where customers have no direct interaction with the e-vendor, trust in website and trust in e-vendor coexist. With different psychological underpinnings, technology trust and interpersonal trust complement each other and jointly affect user behaviors. To study trust in IT/IS contexts, one should not isolate technology trust from interpersonal trust.

Of course, researchers may pay different attention to interpersonal trust and technology trust, depending on their research interests and trust outcomes that they are concerned. If the researchers are interested in relationship building (e.g., initiating a new relationship or managing an existing relationship with the other human party), interpersonal trust may have a stronger and more meaningful impact on the model. On the other hand, if the technology-related behaviors (e.g., new technology acceptance or continued use) are concerned, researchers may find that technology trust has more significant impact on the research model. However, as discussed earlier, both technological artifacts and human actors play roles in building the overall trust in an IT/IS context, and thus IS trust researchers need to keep both types of trust in mind when predicting trust outcomes. For example, in this chapter, to explore the role of trust in design and use of IT/IS, technology trust may play a dominant role in the model, while the influence of interpersonal trust cannot be ignored.

We have discussed technology trust in the previous section. Interpersonal trust has been widely studied in the traditional trust research. In the IT/IS design and use processes, the human actors could be individual persons, like specific e-sellers in C2C e-commerce or certain IT specialists. In other cases, they are groups or organizations that render significant influences on the technology performance, such as IT department, software provider companies, senior management, etc. Trust established toward these individual or group human actors is based on their competence in performing their own responsibilities, and mostly their volitional attributes including benevolence and integrity.

The performance and outcomes of a technological artifact can be affected by different human actors. In organizations, for example, IS are used to support communication and collaboration between remotely distributed parties, to complete certain tasks that usually require human knowledge and labor, and to support integrated operations or processing. The human trustees in these contexts could be the collaborating partners, system designers and sponsors, and other users who have inputs to the systems. There could be a single human trustee considered in a context. For example, to use a personal service tool like a tax e-filling program, in addition to evaluating the trusting attributes of the program itself, a user may also research about the program providers' (e.g., TurboTax and TaxCut) reputation. In some other contexts, users may need to consider more than one human trustee. In the example of accepting and using an enterprise system, beyond the system itself, users have to trust the enterprise resource planning (ERP) vendor to provide a quality system and related services. They have to trust the in-house IT staff for technical support, and they have to trust all other users to provide the system with quality input. If any of these forms of trust is lacking, it may cause user resistance to the system.

To study trust in IT/IS contexts, researchers need to specify, case by case, the human trustees who affect the performance and outcomes of the technology.

In an IT/IS context, technology trust and interpersonal trust usually interact with each other. There are mutual relationships between the two dimensions of trust—one reinforces the other. For instance, users' trust in Microsoft, based on its reputation and market share, ensures their trust in the Office products; on the other hand, if a user loses trust in a software product because of a bad experience, it will impair his or her trust in the software provider too. The strength of the mutual impacts between technology trust and interpersonal trust may vary across contexts. Depending on the contexts and the research interests, researchers may be able to specify the primary and secondary influences between the mutual relationships.

41.2.3 Levels of Trust

Trust in IT/IS contexts is multidimensional as different technological, human, organizational, and environmental factors and attributes contribute to building the overall trust. The trust dimensions exert different impacts on the technology use. It is important to distinguish the levels of the trust dimensions in order to understand their relative influences and build a comprehensive understanding of trust in IT/IS contexts.

Barber (1983) articulated two levels of trust in social systems—general trust and specific trust. In a social relationship, general trust deals with the expectations of "persistence and fulfillment of the natural and moral social orders (p. 9)," which reduce complexity in life and allow effective and moral human actions to continue. The objects of general trust are usually foundational and environmental elements. In an IT/IS context, general trust include users' expectations on the technology infrastructure and those on the institutional structure and mechanisms. Established general trust upholds a supportive and dependable environment for all technology and system uses.

Specific trust was defined as expectations of "technically competent performance" and "fiduciary obligations and responsibilities" of a specific party with which a trustor interacts (Barber, 1983, p. 14). These expectations determine the trustor's attitudes and actions toward a specific party. In the IT/IS context, specific trust deals with users' expectations on the IT artifacts and human actors that they interact with and that influence the task performance and outcomes. It directly shapes users' attitudes and intended behaviors.

General and specific levels of trust are distinct in nature and serve different purposes. General trust reflects beliefs about the normality and stability of a situation, while specific trust is extended toward an actual partner in a social relationship (Barber, 1983). General trust is the precondition and foundation to establish special trust. Users who do not trust the technological and institutional environments would not trust any technology or system used in this environment. On the other hand, specific trust mediates the influences of general trust on the technology-related behaviors. In a trusted organizational and technological environment, users are more likely to trust the particular technology or systems, as well as the human actors involved in the technology use, which in turn, form the IT-related behaviors.

Specific trust dimensions in IT/IS contexts have been discussed in the previous section, including technology trust and interpersonal trust. As for general trust, two environmental trusting objects should be considered. They are IT infrastructure and institutional structure. *IT infrastructure* (consisting of networked computer hardware and software) is the foundation of all kinds of systems use. Users expect to see stable and secure infrastructure in place and proper protocols and up-to-date technical mechanisms and safeguards being used. When the users believe that the IT infrastructure can support fast and accurate computing, easy and secure data storage, and reliable transmission, it becomes simple for them to form specific trust in this technological environment.

Institutional structure refers to the organizational infrastructure as well as social rules, regulations, guidelines, and mechanisms that are followed in an organization to ensure the proper human procedures in the technology use. The effective use of these mechanisms and safeguards promotes users' trust

in such organizational environment. When the users believe that there are effective ways to guide and regulate human actors' role, rights, and responsibilities in the technology use, they will trust the environment, and then are more likely to trust specific system used in the environment.

Trust in these two environmental objects can be called IT infrastructure trust and institutional trust. In the previous research, which mostly focuses on the specific trust, IT infrastructure trust and institutional trust were, if not overlooked, usually viewed and studied as antecedents of trust. Now with a broader view of trust in IT/IS contexts, they are users' trusting assessments on the bigger environment, and these trusting assessments contribute to the overall trust that users establish in the contexts. In addition, some empirical studies have operationalized and measured IT infrastructure trust and institutional trust with scales similar to those of specific trust (Pavlou and Gefen, 2004; Li et al., 2012). Thus, it is reasonable to see them as trust dimensions—the dimensions of general trust.

General and specific trust dimensions form differently. General trust is usually developed based on prior or related experience. In an organizational context, for example, if users have knowledge and experience with the technical and institutional mechanisms from using other systems or in other organizations, general trust can be easily and quickly extended to the current context. On the other hand, specific trust mostly relies on situational factors and requires current and more relevant information processing germane to the specific trusting objects. It is usually less extendable, which explains why most existent research interests are focused on studying specific trust. However, to investigate trust in IT/IS contexts, researchers should not overlook the impacts of general trust dimensions.

41.2.4 Trust Framework in IT/IS Contexts

To summarize the previously discussed trust concepts and constructs, Figure 41.1 presents an overarching framework of trust in IT/IS contexts. Trust in such contexts is multidimensional. Related trust dimensions can be classified in two levels. The general level of trust, including IT infrastructure trust and institutional trust, was built toward the overall environment of technology use. A stable, supportive and well-regulated environment promotes the specific level of trust—technology trust and interpersonal trust. These two specific trust dimensions interact and reinforce each other, and they jointly determine the trust outcomes of interest, such as relationship-building behaviors or IT-related behaviors. In this chapter, to explore the role of trust in the design and use of technologies and systems, the following discussion will focus on IT-related behaviors as the trust outcome, such as new technology acceptance or continued technology use.

This framework develops a comprehensive view of trust in IT/IS contexts. It integrates major trust concepts and constructs studied in previous research such as trusting beliefs and trusting behavior, trust antecedent and trust outcome, trust dimensions and trust levels, etc. It helps cumulate the existing research findings and guides the future trust investigations in IT/IS contexts.

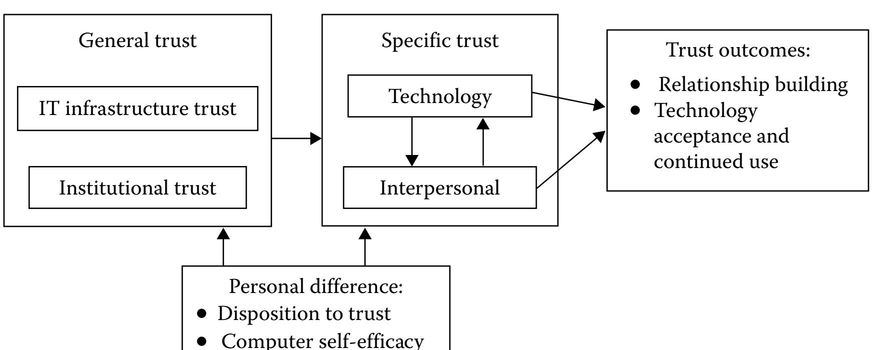

FIGURE 41.1 Framework of trust in IT/IS contexts.

The other constructs included in this framework are disposition to trust and computer self-efficacy. *Disposition to trust* refers to one's propensity to trust others (McKnight et al., 2002). *Computer self-efficacy* was defined as the self-judgment of one's capability to use computer technology (Compeau and Higgins, 1995). They have been included as antecedents to trust in many research studies, especially in the initial trust situations. Examining trust caused by personality traits and individual differences is interesting, but these constructs may provide limited implications to both the trust research and the practice that attempts to cultivate or manipulate trust in the design and use of IT and IS. In future trust research, they could be included in research models as control variables.

41.2.5 Longitudinal Nature of Trust

Trust also has its longitudinal nature. It evolves gradually along with the development of the relationship. Trust built in the early stage of a relationship, without much history and direct knowledge involved, is termed *initial trust* (McKnight et al., 1998). Over time, along with the relationship development, the trust evolves based on firsthand interactions and increasing knowledge between the two parties. It is called *developed trust*. This nature applies to trust in IT/IS contexts too. Initial trust is usually needed to justify new technology acceptance, while developed trust shaped the attitude and behavior of continued technology use.

To study IT/IS trust in initial and developed trust situations, researchers can expect the framework of trust as shown in Figure 41.1 to work differently. As mentioned earlier, in an initial situation, users may rely more on the peripheral trust dimensions to make their technology acceptance decision. Without direct knowledge and experience with the IT artifact, users may temporarily assume the specific trust based on their trusting perceptions of the institutional and technological environments. In addition, trust in related human actors may have a strong impact in promoting technology trust and dominantly determine users' technology acceptance behavior. However, once a technology has been adopted, along with the continuous interaction and increasing knowledge of the technology, many relationships in this framework may change. In a developed trust situation, users rely more and more on their trust judgment in the technology itself. The specific trust may depend less on the general trust, and the technology trust may depend less on the interpersonal trust. Users' real-time trust evaluation of the technology, which has been confirmed or denied in each and every use of the technology, becomes the key determinant in users' continued technology use (Bhattacherjee, 2001; Thatcher and McKnight, 2010; Li et al., 2012).

41.2.6 Uses of the Trust Framework

The framework of trust contributes to the IS trust research in different ways. It helps organize the existing literatures and provide a comprehensive guide for the future trust investigation in the IT/IS contexts.

First, the framework of trust provides a structure to map out the previous studies with distinct foci and lenses and to develop the streams of the IS trust research. For instance, studies that investigated virtual team trust (Jarvenpaa et al., 1998; Sarker et al., 2003; Robert et al., 2009) and customers' trust in online product or service providers (Jarvenpaa et al., 2000; McKnight et al., 2002; Gefen et al., 2003) mostly focused on interpersonal trust in the IT/IS contexts, while studies that examined trust in organizational IS (Li et al., 2009), inter-organizational systems (Ratnasingam, 2005), online RAs (Wang and Benbasat, 2008), and personal productivity software (McKnight et al., 2011) explored technology trust. Both streams have their foci and contributions to the field, but both of them only see one side of the overall trust in IT/IS contexts. A new stream of studies is being developed that models both interpersonal trust and technology trust in its trust investigation (Thatcher and McKnight, 2010; Li et al., 2012). They examine the interaction and the relative impacts of the two trust dimensions to the trust outcomes.

Another stream of the IS trust research is to explore the formation of the specific trust (i.e., interpersonal trust and technology trust), among which many studies examined IT infrastructure trust (Lee and Turban, 2001; Suh and Han, 2003) and institutional trust (Pennington et al., 2003; Pavlou and Gefen, 2004)

and their influences in forming the overall trust in certain IT/IS contexts. Other streams are to explore the trust-inducing features from the interface design perspective (Wang and Emurian, 2005; Li et al., 2009). Features that hint the effectiveness of the infrastructure and institutional controls can strengthen the link between general trust and specific trust and induce trust for new technology adoption.

Second, this framework of trust also provides guidelines to the future IS trust research. To investigate trust in IT/IS contexts, researchers need to know the multidimensional nature of trust and adopt a broader view in examining the contexts. Their studies can focus on one or a few trust elements depending on their research purposes and interests. But, when designing the studies and interpreting the research findings, researchers need to keep a bigger picture in mind and control the impacts from the other trust elements. On the other hand, while most of prior research had scrutinized individual trust elements, the framework of trust suggests that additional research attention is needed to address the links among the trust dimensions. Their interactions are keys to improving our understanding of trust and manipulating trust to achieve desired outcomes in certain IT/IS contexts. Additional and detailed suggestions to the future research are discussed in Section 41.4.

41.3 Implications to the Practice

The trust framework presented in Figure 41.1 provides not only the base for trust scholars to cumulate the literatures and develop trust theories in IT/IS contexts, but it is also a platform to inspect the impact of IS trust research on the practice. Existent trust studies have provided valuable implications and useful directions to guide the design and use of IT and IS in an organizational environment.

41.3.1 Cultivating Trust in SDLC

Trust can be cultivated in the design process. To obtain a system, whether it is an in-house development, a purchased system, or an outsourced project, organizations need to understand and accommodate the trust-inducing elements in the systems development process. Specifically, additional attention on user involvement, help feature development, and documentation process in the system development life cycle (SDLC) can help cultivate user trust in the future system. Many of the trust-building techniques are also applicable to modern SDLC models, such as agile software development, rapid prototyping, etc.

User involvement in SDLC has been well known as an effective way to improve system quality. Users are invited to help with business requirements identification, to contribute opinions on desirable functions and features, and to participate in system testing. It narrows or closes the possible gap between the system capability and the organization's requirements. User involvement in SDLC also helps cultivate user trust in the final system.

First of all, early involvement of users in the system design and development process facilitates a positive and healthy user relationship with IT staff and other stakeholders of the system, and thus promotes interpersonal trust needed in future system use. The in-house IT staff, external IT consulting and support group, and other stakeholders, like system sponsors, senior management, and other users, could be the major human actors that affect users' perceptions of the future system use and performance. In many organizations, users may not have much coworking history or more friendly contexts to know IT staff other than in emerging troubleshooting situations. They may not even have a direct interaction or knowledge of other stakeholders in the system use either. A solid base for users to build trust in these human actors is missing. Early user involvement in SDLC provides opportunities for the users to meet and know the internal and external IT staff and system stakeholders in person before the actual system use. With a prolonged collaboration and personal interaction, it is more likely for them to establish a healthy and trusting relationship with these parties toward the future system use.

Second, user involvement in SDLC helps implant the desired trusting attributes into the system and thus promote users' technology trust. With a diverse knowledge background, system users may have different perceptions on the useful and important system functions and features than IT professionals.

They may also have their own judgment on system functionality, reliability, and helpfulness. It is important to facilitate early communication between IT professionals and system users and allow them to exchange their points of view. Specifically, users' opinions should be considered in the system defining and business requirement analysis stages to include user-desired trusting attributes of the system. In the meantime, IT professionals can help users shape their expectations and develop a realistic view of the system.

User involvement should also be encouraged in the system testing phase. A successful example is Microsoft, which expanded their testing of Office 2010 by preleasing a beta version to an expert user group and an experienced user group. They used the users' feedback to learn about potential difficulties and support needed in using the product. They also used the users' comments on the likes of the product in their market research and crafted a successful launch of the actual product the year after (Kroenke, 2011). User involvement in the system testing helps to engage external users and enhance user trust in the future systems.

In addition, user involvement in SDLC helps develop a feeling of ownership and a reasonable expectation of the final system. Previous research (Lewis and Weigert, 1985) has posited that trust has its affective base, which is complementary to the cognitive base. It is more likely for the users to grant trust to a system to which they have contributions and commitment in the development, than the one that they are simply given and asked to use. Also, user involvement in SDLC reduces the possibility of over- or underexpectations from third-party advertising and promotion, and helps users develop reasonable and accurate beliefs to the system in order to form trust.

To an outsourced project or a purchased system, it is beneficial to involve users in the vendor or contractor selection process. When users have a chance to participate in or just observe this process, they will have a better source to assess the quality of the system. On the other hand, it will increase users' affective trust in the future system, because it is developed and supported by the vendor or contractor they self-picked.

System designers and developers should understand the keys to users' technology trust and specifically address each of the trusting beliefs in the system. The importance of functionality and reliability of a system has been well understood and addressed in the system design and development process. Additional attention should be placed on the helpfulness features. Beyond the external help, like technical training and support, modern users with faster working pace and increasing computer self-efficacy have growing interest in using self-help features provided in the system or other self-serviced resources such as online user forums. System developers could enhance the self-help features and support the development of the peer-assisting services with the system. In systems interface design, help buttons should be placed at noticeable and convenient locations. Multiple ways to reach the help topics of interest should be provided (e.g., indexing contents, keyword search, and fuzzy search), and help should be provided in a more intuitive way with choices of elucidation methods (example analysis, video tutorials, etc.). User-generated content (UGC) is another way to improve helpfulness of a system. Online user forums that allow experience sharing and peer user assistance have become a popular and effective way for users to find help. System developers and sponsors could encourage user forums, and actively participate to monitor and guide the forum development.

In addition, system documentation is important in cultivating user trust. Users' expectations to the system are usually formed based on the predefined responsibilities of the system. Before and during the actual use, system responsibilities should be clearly stated and well communicated to all users in order to establish reasonable and realistic expectations. The system documentation, such as a handbook, training materials, etc. has the most authority in defining system responsibilities. Careful and thorough documentation and adequate communication will facilitate and guide a comprehensive and healthy user expectation development to form trust.

41.3.2 Promoting Trust During System Use

Once a system has been obtained and implemented, trust could be fostered to reduce user resistance and promote initial system acceptance and continued use. The current IT/IS trust literatures provide

implications to the practice of fostering trust in system use too. Depending on the system use history and the trust development stages, the literatures suggest different focuses to promote user trust.

To promote a new system, organizations could place the attention on developing and advertising the general trust, as users usually lack the direct knowledge base to develop specific trust in such circumstances. Supportive and tech-savvy organizational culture, stable and well-regulated environment, and infrastructure are essential elements for a successful system acceptance. For example, to promote general trust in an organizational IS context, the organization needs to have well-defined technology-use and data policies, which should be thoroughly communicated and strictly enforced. Users should be well educated about organizational mission and goals and its technology strategies. These elements help construct a trustworthy environment for general technology uses.

Establishing such environment could be a long-term process that requires continuous inputs. In the meantime, particular technical safeguards and institutional mechanisms can be used as an immediate booster of users' trust in the environment. For example, recent research (Li et al., 2012) has suggested that third-party authorization and certification programs such as TRUSTe, BBB Online, and VeriSign could provide instantaneous assurance to customers' trust in the overall e-commerce society. New or small e-vendors could rely on these programs to promote customers' specific trust and encourage the first purchase. In different technical contexts, system designers and sponsors need to carefully identify effective technical and institutional mechanisms and use them to ensure initial trust and promote new technology acceptance.

After the initial system adoption, organizations should turn their attention to the specific trust dimensions in order to escort the continued system use. When users have started to use the system, they will turn to each and every interaction with the system and the outcomes of each system use to form trust. If their initial trusting perceptions get confirmed and the task outcomes are satisfactory in each of the system use, they will form developed trust, which suggests continued use of the system (Bhattacherjee, 2001). Of course, if their actual experiences suggest different or negative perceptions of the system, or the task outcomes are not as they expected, their developed trust will be low and will cause resistance to continue using the system. In the developed trust stage, users usually depend less on the environmental factors. It does not mean that the organizational and technological environments, as well as the technical and institutional safeguards, are not important anymore. They are still the precondition of the user trust, but they would have limited effects to increase the specific trust or promote continued system use. To foster or reinforce users' developed trust needed in such situations, organizations should focus their efforts on guiding and supporting each of user–technology interactions.

Specifically, IT professionals should work their best to bring productive and pleasant system experiences to each user. Thorough user training and real-time technical support are critical to ensure smooth user experiences and help users develop positive beliefs in the quality and usability of the system. Proper system maintenance and backup should be administered regularly to reduce the system downtime or recover quickly from system failures.

In addition, individual users may only use a small portion of the system in their jobs. Without a strategic and overall view of the system, they may form trusting beliefs based on fractional perceptions. In this case, system sponsors are responsible to educate users and help them see the complete and strategic value of the system to the entire organization. It may help individual users overcome their learning curve to continuously use the system.

41.4 Research Issues and Summary

This chapter reviewed the underlying principles of trust research in IT/IS contexts and presented an overarching framework of trust. The framework integrated major concepts and constructs in the existent trust literature. It is intended to help develop a comprehensive understanding of trust that facilitates trusting behaviors, especially technology acceptance or continued technology use in organizations. It provides a platform to cumulate research findings and develop theories in this field. This framework also helps identify several research issues and suggests future directions to the IS trust researchers.

First, the trust framework suggests a broad and comprehensive view to investigate trust in IT/IS contexts. With a broad view, researchers may be able to adopt different perspectives to answer a research question. Specifically, prior research has chosen the primary trust dimensions to study trust outcomes of interest. It will be interesting to explore the impacts from the other trust dimensions to the same trust outcomes. For example, prior studies mostly focused on technology trust when they investigated IT-related behaviors as the trust outcome. Now, based on the interaction between the two specific trust dimensions posited in the trust framework, it will be interesting to see how to manipulate interpersonal trust or how to facilitate the trust transference from trusted human actors in order to promote technology trust. What individual or organizational characteristics could induce users' trust toward a certain technology artifact? What features and information can be incorporated in the system design and use process to effectively transfer trust from a well-known and reputable software vendor or contractor to a new system? These sample research questions can bring new insights to the technology trust research.

The trust framework classified trust dimensions using general trust and specific trust, and suggested the interactions between these two trust levels. As discussed earlier, general trust provides the precondition and the foundation to build specific trust, especially in new technology acceptance situations. Prior research does not pay enough attention to general trust because it usually has less direct impacts on the trust outcomes. However, once a trustworthy environment is established, it will have long-term benefits to all technology use in the organization. Thus, future research could investigate general trust, including how to cultivate trustworthy organizational and social environments, and how to manipulate general trust to promote specific trust and to achieve the desired trust outcomes. A more applied research direction is to suggest effective procedures and practices and technical and institutional mechanisms to construct a trustworthy environment for system acceptance. Interface design research is also needed on how to cue the users about the established and trustworthy environment.

Recent trust research has introduced novel methodologies to the IS field. Dimoka (2010) and Riedl et al. (2010) used functional neuroimaging (fMRI) tools to explain how trust was formed biologically with various brain functions. This method provides a unique and novel perspective to study trust and explain trust formation. It can be used along with the trust framework to investigate trust in IT/IS contexts. For example, trust developed toward different objects in such contexts may differ in terms of the activation of the brain functions. It will be interesting to see the neural differences in forming the distinct trust dimensions, which may provide fresh implications in designing and using IT/IS in practice.

A thorough understanding of trust in IT/IS contexts provides a solid base in research endeavors that applies the concept of trust in larger nomological networks or in the different fields. Previous research has combined the trust model with the other technology theories, such as TAM (Gefen et al., 2003, Benamati et al., 2010). Other research studied trust with related concepts such as risk and expectation in a technology context (Luo et al., 2010). In many cases, trust is one psychological factor that plays certain role in a more complex situation. Thus, trust can be included in other theories and models to help improve the understanding in different domains. In these cases, it may not be appropriate to include a complete trust framework like what this chapter presents. But a thorough understanding of trust based on this framework can suggest the best parsimonious way to operationalize and measure trust in different research domains.

Impacts of Information Systems on Decision-Making

42.1 Introduction

The promise of computer aids has captured the imagination of human inventors through numerous decades. Decision aids have the potential to free humans from mundane and tedious tasks, increase human productivity, and minimize human error. Decision aids appear in innumerable applications as varied as automobile manufacturing, airplane piloting, car navigation, corporate payroll management, and nuclear reactor management (Benbasat et al., 1993; Hayes-Roth and Jacobstein, 1994; Skitka et al., 2000). In fact, some researchers suggest that intelligent decision aids may be employed to assist human users in almost any environment imaginable (Russell and Norvig, 2003).

Since the early work on identifying the strengths and weaknesses of decision aids and their human operators (Fitts, 1951), there has been substantial literature regarding how people use information technology (IT) to improve their decisions. This literature spans decades and disciplines (e.g., psychology, computer science, management information systems [MIS]), and we cannot hope to offer a comprehensive review of all literature in this area in a single chapter. However, we will attempt to review key aspects of computer-aided decision-making with an emphasis on the impacts of decision aids on the decision-maker and focus especially on research published in MIS journals.

To examine current knowledge related to computer-aided decision-making, we first review key concepts in unassisted decision-making. Our approach is strongly anchored in the cognitive area of decision-making research. We acknowledge important work concerning decisions based on emotion and affective computing, but this work is outside the scope of this chapter. With this direction, we first describe a four-phase model of decision-making. We then discuss how decision aids affect decision-makers in each phase. Relevant findings are reviewed in terms of potential benefits and pitfalls for decision-makers.

42.2 Phases of Decision-Making and Technology Support

To understand how information systems impact human decision-making, we decompose decision-making into four simple steps: *information acquisition*, *information analysis*, *decision selection*, and *action implementation* (Parasuraman et al., 2000). These four steps are mostly analogous to those (i.e., intelligence, design, choice, and implementation) in the four-step decision-making model of Simon (1977). Although some cognitive psychologists may consider this four-phase model (Figure 42.1) a gross oversimplification, it is consistent with basic decision theory (Broadbent, 1958) and accurate enough to be useful for studying the role and design of IT support in human decision-making (Parasuraman, et al., 2000).

During each of the four phases of decision-making, IT support may play a significant role, a minor role, or no role at all. Parasuraman et al. (2000) have characterized the level of support IT can provide during each decision phase, as shown in Figure 42.2. Thus, a decision aid can be characterized based on the level of support it provides during each decision phase.

IT can support human information processing in all of these phases (Parasuraman, et al., 2000). We refer to such support as "decision support" in general, regardless of which phase it affects. Decision support can utilize IT to a varying extent such that the decision aid can decide everything without involving the user (i.e., full automation), or the user can make all decisions and take action with little assistance from the system. Parasuraman et al. (2000) treat these two extremes as the ends of a 10-level "automation" continuum. For the sake of simplicity, we assume three levels of automation: low, moderate, and high.

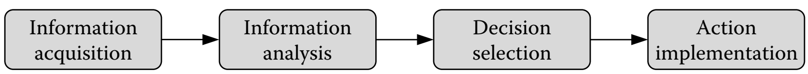

FIGURE 42.1 Four-phase model of decision-making.

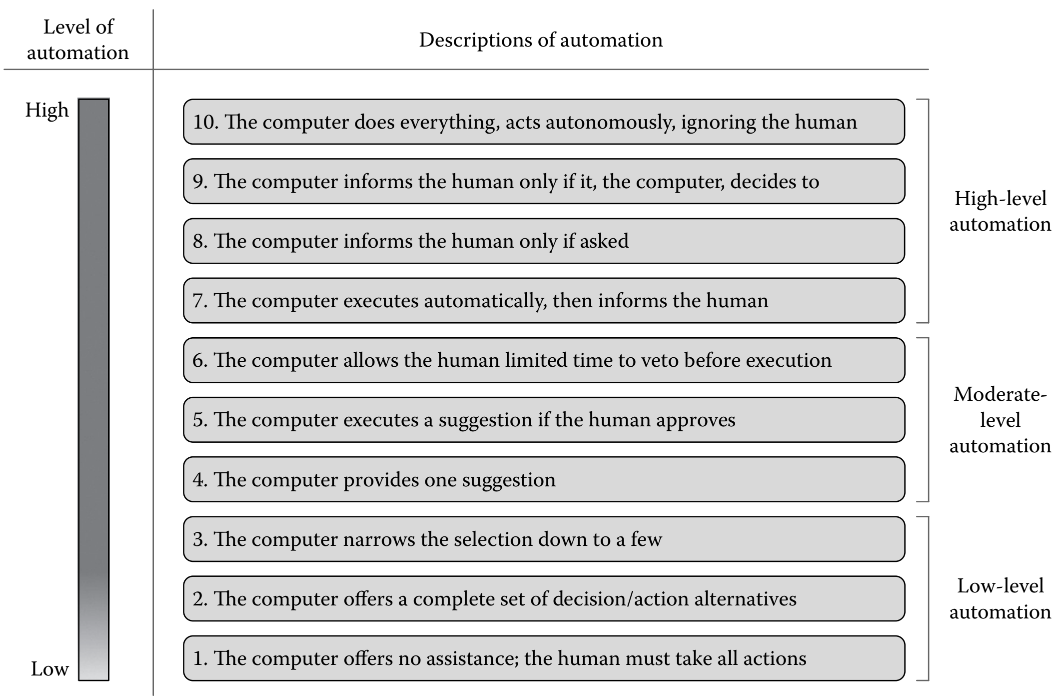

FIGURE 42.2 Descriptions of automation.

As one transitions from low to high levels of decision support through automation, the role of IT changes from assisting the user to advising or replacing him or her. Low decision support refers to situations in which the user performs the bulk or all of the decision-making. At this level, IT can provide support by acquiring, aggregating, and/or summarizing the information required for the decision or by providing several courses of action to choose from. Moderate levels of decision support imply more involvement of IT, such as suggesting decision alternatives. The system can provide the logic behind these alternatives and report their likely outcomes, assisting the user in making a better-informed decision. High levels of decision support require little or no input from the users. At this level, the decision aid can fully process the information and make a decision on its own. Users' involvement can be limited to selecting a decision logic or monitoring the decision aid's actions. In the case of complete automation, user involvement may not even be required before the system executes its decision. Examples of decision aids discussed in MIS research are summarized in Table 42.1. These examples span the four decision phases and the levels of automation.

TABLE 42.1 Examples of Decision Aids

Decision Phase	Level of Support	Reference	Task	System Description
Information acquisition	Low	Chervany and Dickson (1974)	Production, inventory, and workforce planning	The system provided statistical summaries of production costs, production amounts, inventory, and labor utilization
	Moderate	Poston and Speier (2005)	Designing a work plan for data modeling	The system enabled searching among existing work plans and provided detailed information and content ratings
	High	Price and Shanks (2011)	Rental property selection	The system enabled searching by attributes among properties, provided data quality tags, and sorted the results
Information analysis	Low	Hoch and Schkade (1996)	Evaluating loan applicants	The system approximated financial performance indicators (e.g., debt ratio and cash flow)
	Moderate	Goodwin (2005)	Adjusting production	The system provided statistical forecasts of future demands
	High	Nah and Benbasat (2004)	Financial analysis	The system (FINALYZER) performed several subanalyses in terms of liquidity, capital structure, and profitability and provided detailed explanations
Decision selection	Low	Wang and Benbasat (2009)	Choosing a digital camera	The system ranked cameras by attribute levels, depending on users' preferences
	Moderate	Eining and Dorr (1991)	Payroll evaluation	The system suggested a numerical evaluation of the internal control over payroll and displayed the rules for its decision
	High	Nissen and Sengupta (2006)	Supply chain management/procurement	The system (Intelligent Mall) analyzed quotations and recommended products and sources using analytical methods and heuristic rules
Action implementation	Low	Lerch and Harter (2001)	Mail sorting/planning	The system enabled users to assign mail to the sorting machines
	Moderate	Cummings and Mitchell (2008)	Unmanned air vehicle control	The system notified the user that it was going to take an action and gave him/her a limited time to veto the decision
	High	Nissen and Sengupta (2006)	Supply chain management/ordering	The system (Intelligent Mall) placed a purchase order and executed the final transaction

42.2.1 Information Acquisition

The first stage of the IT supported decision model, *information acquisition*, deals primarily with sensory processing as decision-makers gather information about their surrounding environment through sensory receptors. This information then serves as the input for the decision-making process.

It has long been known that computer-based decision aids can assist in the acquisition of information. In early considerations of the proper division of responsibilities between humans and machines, machines were thought to excel at data collection (Fitts, 1951). As early research on air traffic control evolved, the value of decision aids in the information acquisition was confirmed, and now decision aids play a crucial role in this labor-intensive task (Wickens et al., 1998). Over time, the ability to aggregate relevant information on which to base decisions has increased with some single decisions (e.g., hurricane forecasts) supported by terabytes of information (NCDC, 2010). A low-level decision aid can merely summarize the information required to make a decision (Chervany and Dickson, 1974), whereas a high-level aid can rank and sort this information, and enable parametric searches (Price and Shanks, 2011).

42.2.1.1 User Benefits

42.2.1.1.1 Better Sensing

MIS research has clearly indicated significant benefit from decision support during information acquisition. Much of this benefit has been achieved by extending the capabilities of human operators. For example, decision aids have clearly demonstrated value in gathering information through additional sensors or searching techniques that are unavailable to human operators. Examples include decision aids that use radars, infrared sensors, and robots with artificial visual and haptic sensors. Decision aids then supply this information to human decision-makers (Parasuraman et al., 2000).

42.2.1.1.2 Easier Information Gathering

Another way that decision aids facilitate information acquisition is through mimicking the actions of a human operator, but more quickly than a human can perform, or on a larger scale. In a recent example concerning computer-aided credibility assessment during a face-to-face interview, a decision aid successfully captured features of one person's behavior during the interview (Jensen et al., 2010). After the interaction was over, the decision aid reported relevant features (e.g., parts of speech, linguistic complexity, gestures, and head movement) it had gathered from the interaction to a third-party observer who had to evaluate the credibility of the interviewee. With sufficient time, the observer could count parts of speech, calculate linguistic complexity, and measure body movement, but this would have been very time consuming for the observer and would delay evaluation of the interview. Other examples can be seen in the procurement context (Nissen and Sengupta, 2006), where users would have to gather, analyze, and compare vendor information manually if not for an automated supply chain management system.

42.2.1.2 Pitfalls

42.2.1.2.1 Identifying Diagnostic Information

In order to be of use to a human operator, a decision aid must gather information that is relevant to the decision. The value of information is often described by how diagnostic the information is, or in other words, how clearly the information indicates an option during decision-making. If information gathered by the decision aid is highly diagnostic, then the decision aid will operate effectively, and the human user will likely benefit from the assistance. If the acquired information is not diagnostic, both the performance of the decision aid and the human user will suffer (Mudambi and Schuff, 2010).

The system's designers (usually in collaboration with the subject matter experts) bear the primary responsibility for determining what information is diagnostic and therefore should be gathered by the decision aid. With some decisions (e.g., a medical inventory alert system), identifying diagnostic information is straightforward, and system designers can successfully achieve a high degree of reliable automation (Chen et al., 2011). However, with other especially complex, naturalistic decisions (Orasanu and

Connolly, 1993) or decisions involving a great deal of ambiguity (Nissen and Sengupta, 2006), acquisition of diagnostic information plays a critical role, but is rarely clear cut. For example, in the case of computer-aided credibility assessment, cues evaluated by the decision aid are probabilistically linked to deception (DePaulo et al., 2003). In other words, the bits of information the decision aid gathers are not diagnostic individually. Only when the information is compiled and combined can they become diagnostic.

The determination of information diagnosticity is possible. When not clearly identified by subject matter experts, diagnostic information can also be uncovered via systematic examination of potentially relevant information. The process for doing so is beyond the scope of this chapter, but we direct interested readers to the work on signal detection (Green and Swets, 1966; Swets, 2000) and artificial intelligence (Russell and Norvig, 2003).

In cases where information diagnosticity is unclear or where resources are not available to determine it, one option that is often adopted is to gather as much information as possible and leave it to the user to determine what is useful and what should be ignored. This practice leads us to our next potential pitfall in information acquisition: information overload.

42.2.1.2.2 Information Overload

One need only type in some common search terms into a popular search engine to experience the sensation of information overload. A simple web search can yield millions of potentially relevant websites, few of which are consulted as part of the search. Information overload was identified in early MIS research as a potential pitfall. In his seminal work on potential pitfalls of decision aids, Ackoff (1967) suggested that information overload was a critical difficulty system users faced several decades ago. This issue is even more of a challenge today, as Paul and Nazareth (2010) demonstrate within the context of group support systems. Managers have no time to pore through all potentially relevant information when making their decisions. Similarly, consumers are not going to read all relevant product reviews before purchasing a product. Ackoff suggested that in countering the overabundance of information, the two most important features of an information system are filtration and condensation. However, filtering and condensing will function well only if they are built on a firm understanding of information diagnosticity. Otherwise, overfiltration and overcondensation of information may occur. In situations where all information could be important and relevant, such as financial fraud detection (Ngai et al., 2011), overfiltration and overcondensation of data could lead users to rely on inadequate information, and thus make incorrect decisions.

42.2.1.2.3 Codifying Errors

Incorrect information stored and codified during acquisition, either as a result of mistakes (Klein et al., 1997) or intentional deception (Biros et al., 2002), is exceptionally difficult for users to detect. These findings echo a well-known cliché in decision aid design: Garbage in, garbage out. However, it appears that once information is codified or stored in a decision aid, decision-makers rarely validate or verify the information. In other words, "garbage" potentially coming from a decision aid will rarely be identified.

To mitigate this pitfall, researchers have investigated the possibility of altering the analysis of information (Jiang et al., 2005) or providing an information quality indicator to inform users of potentially problematic information (Fisher et al., 2003).

42.2.2 Information Analysis

In the second stage, information analysis, information is selectively and consciously perceived, and then processed. Information analysis "involves cognitive functions such as working memory and inferential processes" (Parasuraman, et al., 2000) and refers to the processing of input data in order to make a decision. As with information gathering, there is a spectrum of automated support that an information system can offer a decision-maker. On the low end is simple presentation of relevant information that

was gathered (and potentially filtered) as part of the information gathering stage. An example of a system that provides a low level of analysis capabilities is the one that is used for evaluating loan applicants (Hoch and Schkade, 1996), which calculates and presents several financial indicators. On the higher end of the analysis spectrum is another financial system, FINALYZER (Nah and Benbasat, 2004), which performs several complex subanalyses in terms of liquidity, capital structure, and profitability and provides its users with detailed explanations on these analyses.

The processing capabilities offered by decision support systems offer many obvious benefits. These benefits are widely acknowledged and are relied upon by countless individuals in their daily work and life. However, the processing capabilities of systems also carry some pitfalls, which if left unconsidered, may severely undermine effective computer-aided decision-making. Both benefits and potential pitfalls are addressed in the following sections.

42.2.2.1 Benefits

42.2.2.1.1 Analysis of Relevant Information

Perhaps the most obvious benefit from decision support is the capability to rapidly consider more information than is possible manually, and quickly apply analysis techniques that will yield a reasonable solution. This benefit of decision aids has long been supposed (Fitts, 1951) and is still being supported by current research. For example, a decision aid was able to determine optimal ordering qualities for small manufacturing companies (Choi et al., 2004). Thus, decision aids have the capacity to improve the accuracy of decisions through systematic analysis of relevant information.

Coupled with the potential of increased analysis capabilities, decision aids also offer the promise of decreasing mental effort. Effort reduction is perhaps as important as any gains in decision accuracy. Payne and colleagues (1993) have demonstrated that decision-makers often sacrifice increases in accuracy for a reduction in effort. Early decision theorists termed this tendency *satisficing* (Simon, 1956), where decision-makers adopt an acceptable (although not optimal) choice when they are weighing their options (Newell and Simon, 1972). MIS researchers have noted that computer-based decision aids simplify decisions and reduce the level of effort required during decision-making (Todd and Benbasat, 1991, 1992). Decision aids appear to provide the greatest benefit when users will not or cannot pay sufficient attention to the decision task to make a good choice (Reichenbach et al., 2011). Simply put, users of decision aids are likely to be able to analyze problems in more depth by using the expanded processing capabilities provided by such systems (Hoch and Schkade, 1996).

42.2.2.1.2 Presentation

One of the unique characteristics that systems offer decision-makers is the ability to visualize information in novel or unique ways. When task complexity is low, decision-makers most likely do not require advanced visual elements (Speier and Morris, 2003). However, when task complexity is higher, visualization techniques may assist the decision-maker in identifying links among the information to more easily come to a decision (Speier and Morris, 2003). For example, for complex decisions, a three-dimensional representation of information significantly improved decision performance (as measured by the time spent on analysis) (Kumar and Benbasat, 2004). This is consistent with previous results suggesting that adding visual elements to a decision aid's interface can assist decision-makers when task complexity is high (Speier and Morris, 2003). Other examples include geographic decision support systems (Mennecke et al., 2000), marketing information analysis (Lurie and Mason, 2007), and medical information presentation (Juraskova et al., 2008).

42.2.2.1.3 Feedback

During the information analysis phase, decision aids are in a unique position to offer the user feedback as they consider and weigh relevant information. This feedback may come in one of two forms: a response presented to the user after information is considered (feedback response) and a response to the user about actions that will need to take place (feedforward response) (Arnold et al., 2006; Dhaliwal and

Benbasat, 1996). Both forms of feedback are intended to inform the user about the decision model that the decision aid employs and engender the user's confidence in the decision aid (Dhaliwal and Benbasat, 1996; Gregor and Benbasat, 1999; Kayande et al., 2009). The decision aid's feedback may also instruct the user about analysis techniques that are transferable to other tasks (Arnold et al., 2006). However, in order for decision-makers to improve their performance, an estimate on upward potential (in addition to decision feedback) may be necessary (Kayande et al., 2009).

42.2.2.2 Pitfalls

42.2.2.2.1 Assumptions in Design

In the development of a decision aid, designers may make assumptions about the decision and the information to be analyzed to apply analysis techniques. For example, a designer may specify how to weigh a single piece of information when considering several criteria. Such an assumption may simplify the development of a decision aid and may even be applicable in the majority of cases. However, when assumptions are embedded into the design of a decision aid, problems in the decision aid's operation may surface when the assumptions are violated.

Although this pitfall may seem obvious, it becomes more insidious when one realizes that designers often do not recognize when they are inserting their own biases into the design (Korhonen et al., 2008). To make matters worse, decision-makers who deal with complex decisions are at times unaware of *their own* assumptions (Ackoff, 1967). This renders the task of extracting knowledge from subject matter experts, on whom designers rely to define decision parameters, especially difficult. The end result of unacknowledged assumptions in the design of a decision aid is improper recommendations where the decision aid may actually mislead the user, instead of assisting him or her. The impact of this pitfall will depend on the extent of assumptions and the consequences of the decision.

42.2.2.2.2 "Broken Leg" Phenomena

A special case of making assumptions in design merits singling out. This assumption is based on designers' beliefs that they have considered all necessary information to arrive at an optimal recommendation for the user. This is a common simplifying assumption that significantly reduces the design complexity of a decision aid. But, this assumption leaves a significant vulnerability against which the user must remain vigilant. As famously illustrated by Meehl (1954), assume that a person nearly always (say, 90% of the time) goes to the movies every Tuesday night. To build a decision aid predicting the person's appearance at the movie theater every Tuesday would be straightforward. But assume that the person just broke her leg. A broken leg would likely be outside the consideration of the decision aid but extremely relevant for the outcome. Therefore, the utility of the decision aid would substantially diminish in this case.

42.2.2.2.3 User and Task Characteristics

A great deal of research has explored how user characteristics impact how the user interacts with the decision aid. Expertise was among the first user characteristics considered by MIS researchers, and it was discovered that novices tended to request more information from the decision aid (Benbasat and Schroeder, 1977). In later works, other researchers have illustrated the importance of fit between the cognitive representations of users and capabilities of the decision aid (Goodhue and Thompson, 1995; Vessey and Galletta, 1991). In a review of relevant literature, Zmud (1979) suggested that cognitive behavior of future users should determine the system design. These findings suggest that if cognitive characteristics of users are not taken into account during the design, the decision aid could fall short of its potential to assist users. However, some researchers have suggested that cognitive characteristics of users are of minor importance (Huber, 1983), and other researches have shown no difference in decision improvement among those with high and low cognitive abilities (as measured by working memory) (Lerch and Harter, 2001). However, at this time, it appears that task characteristics are more predicative than characteristics of individual users (Davern et al., 2012).

42.2.3 Decision Selection

During the third stage, decision selection, a single option is selected from among the decision alternatives. The role of the decision aid in this stage of the decision process involves "varying levels of augmentation or replacement of human selection of decision options with machine decision making" (Parasuraman et al., 2000). A decision aid providing multiple decision alternatives is an example for low-level support. In this case, the user would have to pick a solution among the alternatives. For example, the recommendation agent in Wang and Benbasat (2009) provides the users with a list of products that it sorted according to users' preferences, and the users select one. A decision aid offering a moderate level of automated support can provide a recommendation and explain the logic behind it, for example, the expert system that suggests an evaluation of the internal control of a factory payroll (Eining and Dorr, 1991). The users can, in this case, view the explanation for the rules that the expert system used to determine this recommendation, and they can choose to agree with the recommended evaluation or create their own solution. A decision aid can also provide high-level support by following a series of rules and making a decision on its own. For instance, the fully automated supply chain management system, Intelligent Mall (Nissen and Sengupta, 2006), can analyze supplier quotes and recommend products and sources, without any requirement of human involvement.

When the information analysis stage of the decision produces an unambiguously superior option, decision selection may be a simple matter that can be rapidly carried out without much supervision. However, when information analysis does not produce a superior option or the information analysis and gathering is somehow deficient, decision selection becomes much less trivial. High levels of automation during decision selection carry several benefits and drawbacks that are briefly reviewed next.

42.2.3.1 Benefits

42.2.3.1.1 Rapid and Systematic Decision-Making

When the decision parameters are well defined (i.e., when the information gathered is diagnostic and sufficient for the decision), a decision aid featuring high decision selection automation has the capability to rapidly make correct decisions on a scale that a human decision cannot match. For example, many complex tools are available to investors that constantly poll and immediately react to price changes in securities. In a similar example, airline pilots rely heavily on rapid control changes from modern autopilot systems. In these examples, decisions are made by systematically considering a significant amount of information and rapidly coming to a conclusion. For well-defined decisions, a decision aid can substantially increase speed and accuracy of these decisions (Parikh et al., 2001).

42.2.3.1.2 Adaptable Decision Model

When a decision is not well defined, the decision model of the decision aid (i.e., how the aid decides on an option) is flexible and not hampered by bias or previous practice. For example, in early decision support research, the designers of MYCIN showed that their decision aid outperformed experienced doctors on a diagnosis task (Shortliffe, 1976). In its diagnoses, MYCIN considered known base rates that were adaptable to whatever the local and current prevalence of disease was. Findings in computer-aided credibility assessment (Jensen et al., 2010) and agent-based negotiation (Nissen and Sengupta, 2006) research suggested a similar conclusion. If a decision model in a decision aid needs to be altered, it is a simple matter. If a decision model in a human decision-maker needs to be altered, it may be more difficult (especially for very experienced decision-makers). Another benefit is that a decision aid may support several different decision models such as normative decision strategies (in place of elimination by aspects) (Wang and Benbasat, 2009) or recognition-primed decision-making (Hoch and Schkade, 1996).

42.2.3.2 Pitfalls

42.2.3.2.1 Complacency

According to Parasuraman et al. (2000), complacency occurs among decision-makers when a decision is highly, but not perfectly, reliable in decision selection. In a review on how decision-makers rely on decision aids, complacency is described as "over-trust" in the decision aid (Parasuraman and Riley, 1997). The decision-maker essentially abdicates decision-making responsibility to the decision aid. What results is a decision-maker who does not notice when a decision aid fails to perform as expected.

The tendency toward complacency is most evident in decision aids with high levels of automation where the user plays more a more supervisory than active role. Some research has suggested that the task of supervision substantially differs from decision-making, in terms of being vulnerable to the negative effects of complacency (Crocoll and Coury, 1990). On the one hand, the tendency toward complacency appears to be rational. After all, why would a user expend cognitive effort checking a decision aid that he or she expects to be right? Complacency becomes a problem however, when the costs of a bad decision are high. In considering an appropriate level of automation to build into a decision aid, Parasuraman et al. (2000) argue that the amount of expected complacency should be one of the primary considerations.

42.2.3.2.2 Reliance on Heuristics

A closely related issue to complacency is reliance on decision heuristics during decision-making. In making very complex decisions, individuals often are either not able to or not sufficiently motivated to come to a decision based on evidence and reasoning (Eagly and Chaiken, 1993). Instead, they rely on mental shortcuts such as "the decision aid recommends I should take this action, therefore I will do it." There is no serious consideration given to the reasons behind the aid's recommendation, but it is blindly adopted because investigating the "why" would require too many cognitive resources. Past research has shown that decision-makers depend on cues provided in support of heuristics (e.g., credibility or quality indicators) to a great degree (Fisher et al., 2003; Poston and Speier, 2005). If designers need to use such cues to assist decision-makers, they should take care to ensure the cues are as accurate as possible. Decision-makers will seek to reduce the amount of effort they expend during decision-making (Payne et al., 1993) and will use the cues even if they are far from perfect. Designers should also realize that quick decisions made based on heuristics may come with drawbacks. According to psychology research, such decisions are quickly made but can be transient and unstable (Petty and Cacioppo, 1986a,b). There appears to be a Goldilocks effect for the sustaining decision-makers' systematic processing when they are using a decision aid: not too much support, but not too little either (Tan et al., 2010).

42.2.3.2.3 Recommendation Rejection

After all the effort that goes into designing, developing, and verifying the function of decision aids, decision-makers may still not use the decision aid. The reluctance to use the decision aid may be especially salient among more experienced decision-makers (Jensen et al., 2010; Yang et al., 2012). It is clear that decision aids must create the impression in decision-makers that they are useful and pleasant to use (Kamis et al., 2008). Another way to entice decision-makers to engage more with the decision aid is to solicit their input and incorporate their input in the decision aid's recommendations (Arnold et al., 2006). However, the effects of providing this functionality are still unclear, and for some complex problems may be detrimental to decision performance (Jensen et al., 2011; Lee and Benbasat, 2011).

42.2.4 Action Implementation

Action implementation is the execution of the selected decision. Action implementation has not received as much attention in MIS research as the previous three stages of computer-aided decision-making. However, it deserves consideration because the action is the final outcome of decision-making.

In contrast to MIS research, other research disciplines (e.g., economics) focus solely on the actions. Among the little MIS research that does concern action implementation, there is a spectrum of support from low, for example, a system that enables users to assign mail to sorting machines (Lerch and Harter, 2001), to high, for example, a system that places a purchase order on its own and executes the transaction (Nissen and Sengupta, 2006).

42.2.4.1 Benefits

The primary benefit of high levels of automated support is the removal of the human in carrying out the action. In highly defined tasks such as monitoring (Aron et al., 2011), where the weaknesses of human operators (e.g., vigilance, speed) are the primary threat to successful action implementation, high levels of automation may be desirable and can significantly improve decision-making performance.

42.2.4.2 Pitfalls

The primary pitfall during action implementation is that actions might be carried out in a manner that is inconsistent with the wishes of the decision-maker. Such a situation would be most likely to arise where automation is on the higher end of the spectrum. From the perspective of the decision-maker, unexpected actions would likely be deemed as overreaching (at best) or just plain wrong (at worst). Such actions would also likely decrease users' trust in the decision aid and their intention to use it again in the future (Komiak and Benbasat, 2006). Other considerations for designers planning to implement a high level of automation include the costs and the likelihood of actions being implemented incorrectly. As automated decision aids are being developed for more and more complex problems (e.g., automated equity trading), the action implementation stage of a decision should attract more attention from MIS researchers.

42.3 Future Directions in Computer-Aided Decision-Making

To consider future directions for research in computer-aided decision-making is a little like gazing into a crystal ball. The field is ripe with creativity and innovation, and we are constantly amazed by new approaches that individuals and organizations develop for appropriately supporting decision processes. Nevertheless, several new trends have captured our attention, and we briefly discuss them next.

42.3.1 Decision Support Using Social Media

With the explosion of available information on the Internet and as users everywhere become individual content providers (through contributions to social media, community forums, blogs and microblogs, video sharing sites, etc.), designers of systems are devoting increasing attention to user-generated sources of information and developing tools to summarize and coalesce this information into useful knowledge (Hu and Liu, 2004). Examples include customer feedback and rating systems that online retailers develop (e.g., online product reviews), software performing sentiment analysis and data-driven market research, and location-aware computing. Individuals willingly contribute information about their own experiences and perceptions. This represents a significant opportunity for designers of decision aids as one of the most potent cues that individuals attend to in making decisions is the experience of others who have made the same or similar decisions (Mudambi and Schuff, 2010). For example, over 80% of holiday shoppers turn to online product reviews to assist with purchase decisions (Nielsen, 2008). Another example can be found in selecting a dining option. Combining location-aware computing with online reviews of dining options can effectively guide a decision-maker to a suitable dining option. The existing glut of user-contributed information will only continue to grow, and this presents a significant opportunity for designers of computer-based decision aids. If they can harness the experience of crowds, they will provide a powerful tool in support of decision-making.

42.3.2 Balancing Heuristics and Systematic Decision-Making

With the rising amount of information comes the responsibility of effectively managing it. Given the sheer magnitude of available information at decision-makers' fingertips, it is unreasonable to expect decision-makers to carefully and systematically review all relevant sources when making decisions. It is much more reasonable to expect decision-makers to rely on heuristics (e.g., helpfulness scores or star ratings) or recommendations (e.g., prescriptive advice) provided by a decision aid, because decision-makers likely lack the ability or motivation to examine all relevant sources (Cao et al., 2011). This tendency prompts a significant question that researchers must carefully deal with: Given a context and a decision aid, why do decision-makers reach the decision they do? In other words, what is the basis of a decision-maker's choice? This question is not new (Ackoff, 1967); however, it is growing in importance because the amount of information available to decision-makers makes the effort associated with even the simplest decisions substantial (e.g., Who offers the best Italian food in the city?), and decision-makers increasingly *are not able* to examine all relevant information and *must* rely on a decision aid.

Using heuristics to deal with complex information is actually a natural phenomenon. Even without a decision aid, people tend to rely on several cognitive heuristics, such as representativeness, availability of instances or scenarios, and adjustment from an anchor, in order to simplify complex decision-making tasks (Tversky and Kahneman, 1974). However, even though these heuristics reduce cognitive load and are usually effective, they can (and usually do) result in systematic errors. For example, people typically reach different estimates when rapidly multiplying ascending versus descending sequences of the same numbers. In addition to helping people interpret large amounts of data, decision aids can also help them avoid such cognitive biases and mitigate the resultant systematic errors (Bhandari et al., 2008).

The tendency (and even necessity) of decision-makers to rely on decision aids for assistance with decisions involving massive amounts of data places a great deal of responsibility on the designers of such systems and those who gather and contribute information that is later categorized by the decision aid. Individual decision-makers are unlikely to audit inputs to a system providing a recommendation, but they will likely be able to tell when they have relied upon an incorrect recommendation from a decision aid. Being wrong could carry with it substantial consequences for trust, use continuance and willingness to adopt future recommendations (Komiak and Benbasat, 2006).

42.3.3 Persuasive Technology

With increasingly sophisticated decision aids and the inability or unwillingness of decision-makers to consult relevant information during their decisions, there exists the potential for decision aids to unduly influence our opinions and attitudes (e.g., recommendation agents for commercial products, opinion, and social media aggregators). This possibility has been noted before (Fogg, 2002). But, as decision-makers increasingly become separated from information they would use to make decisions, the potential for manipulation increases.

42.3.4 "Big Data" Analytics

Recent research shows that top-performing organizations use data analytics more and are better at deriving value from analytics (LaValle et al., 2011). Given the increasing abundance of information, understanding and interpreting it becomes much more difficult yet critical, in order to gain a competitive advantage. Finding ways to correctly interpret and extract meaning from "big data" is a key challenge faced by scientists in many fields, and conventional tools may not be adequate to convey understanding of phenomena captured by "big data" (Frankel and Reid, 2008). The role of decision aids in discovering trends, patterns, and relationships in such data and transforming them into business value remains to be further scrutinized and improved, which should yield solid practical implications.

42.3.5 Action Implementation in Natural Environments

Finally, as noted earlier, there is little research on action implementation in technology-supported decision-making. In the MIS discipline, there has been a great deal of research investigating what individuals say they would do (i.e., their intentions). However, past MIS research has also shown that in terms of system use what individuals say they do and what they actually do are sometimes very different (Straub et al., 1995). This facet of supported decision-making deserves additional attention.

42.4 Conclusions

This chapter offers a brief glimpse into the potential benefits and pitfalls of using IT to facilitate decision-making. In countless cases, IT has improved and quickened decision-making. However, designers and decision-makers who rely on IT must also be aware of how decision aids can undermine the decision-maker. Our treatment of computer-aided decision-making has been largely limited to MIS research. However, we hope our treatment effectively illustrates the complexity of computer-aided decision-making. By being mindful of the trade-offs between benefits and potential pitfalls of using decision aids, our hope is that individuals will be able to appropriately rely on IT during decision-making and not misuse or abuse available decision aids.

Computer-Supported Cooperative Work

Steven E. Poltrock
Bellevue, Washington

43.1 Introduction

Computer-supported cooperative work (CSCW) is a field of research addressing the intersection of collaborative behaviors and technology. CSCW includes collaboration among a few individuals, within teams, within and between organizations, and within online communities that may span the globe. CSCW addresses how technologies facilitate, impair, or simply change collaborative activities. It is a broader field than the four words comprising its name suggest. Although its primary focus is on computer-supported activities, it encompasses collaborative activities that have not yet been but could be computer supported. Its focus is on collaboration, but not necessarily achieved through intentional cooperation. Collaborators may compete with one another or may not even be aware of each other. The field's initial focus was on work-related activities, and this remains a topic of interest, but the scope includes collaboration in any area of human endeavor including games and social media.

43.2 Underlying Principles

Collaboration is the central issue in all CSCW research. The key challenge for both researchers and developers is to understand collaboration, how it is accomplished, and its impediments. Sometimes, these impediments include aspects of technologies intended to support it, potentially providing requirements for enhancements or suggesting new technologies.

43.2.1 Classes of Collaboration Context

How people collaborate depends on many aspects of their context. Classification models of collaboration context capture some of the features of this relationship. For example, people collaborate in real time and asynchronously, in the same location or different locations, and in small groups, organizations, or communities, as shown in Figure 43.1. Consider the collaborative activities likely to occur in each cell. A team or *small group* (typically less than seven people) may work together in a team room, collaborating in the *same location* at the *same time* by speaking to one another and by creating and sharing artifacts retained in the room. They are supported by technologies that facilitate small group, face-to-face interactions, such as digital projectors and meeting facilitation tools. Small groups may collaborate from *different locations* using collaboration technologies to communicate and share information with one another. A small group may work together at different times in a team room (*same location, different times*) by accessing or updating information posted in the room. A medical team providing patient care around the clock offers another example of collaboration in the *same location* at *different times*. A small group working together on a multiauthored paper produced by passing revisions back and forth is a familiar example of collaborating at different times and locations.

Larger groups form *organizations* to facilitate coordinated action across all members. Organizations typically contain many small groups that may collaborate in the ways described previously, but we should also consider how these groups collaborate with one another to achieve their common objectives. The collaborative activities of large organizations fall largely into two cells of the model in Figure 43.1. Organizational activities are rarely performed in a single location, because their size and missions demand geographic dispersion. Organizations are likely to engage in complex activities that require that groups work together in *different locations* at the *same time* and at *different times*, and coordinating these activities is the organizational challenge and their reason for adopting collaboration technologies. In a manufacturing organization, for example, collaboration focuses on the product, and group contributions to the product are coordinated by its development or construction plan and supporting technologies.

Communities are collections of people with common interests. Neighborhood communities are defined by their common location, but most communities are geographically distributed. Communities have no organizational structures, although they are often served by organizations that view the community as their marketplace. Collaboration within a community focuses on their common interest and requires little or no coordination. Consider, for example, the community of people interested in photography. Members of this community may seek or share photographs or information about photographic techniques at the *same time* (via presentations) or at *different times*. Organizations develop technologies that support sharing photographs while offering products and services to the photography community.

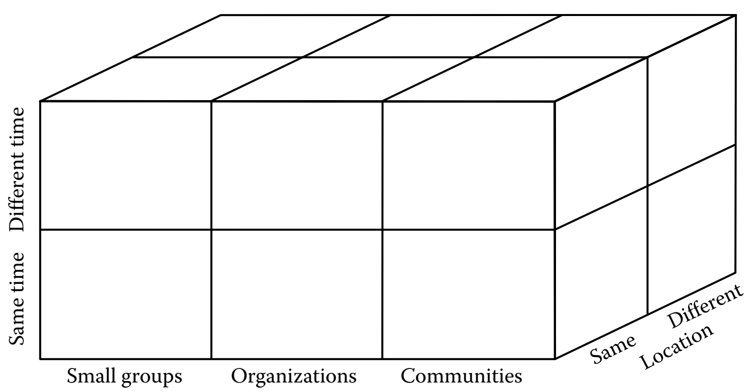

FIGURE 43.1 Classification model of three dimensions (time, place, and social unit) of collaboration context.

Each cell of Figure 43.1 constitutes a substantially different collaboration context, involving different collaborative activities and demanding different supporting technologies. This classification model describes three broad attributes of context (who, when, and where) that are relatively easily categorized. Other attributes of context such as the objectives of the collaboration are more difficult to categorize but no less important.

43.2.2 Categories of Collaboration Activities

The human activities involved in collaboration can be roughly described as communicating (e.g., speaking, writing, reading, listening), sharing information with one another (e.g., displaying a presentation, a map, a document, or other data), and coordinating (e.g., taking turns, sharing a resource, or performing different subtasks). Of course, these categories overlap and are tightly integrated; people may coordinate through speech and share information through both speech and written artifacts. People collaborating engage in all three categories of activity, shifting with little effort from one to another or combining them. Nonetheless, these categories are useful when thinking about technologies that support collaboration. Table 43.1 lists some well-known technologies or technology features that support each category of activities in both same-time and different-time contexts.

The temporal dimension shown in Table 43.1 is, of course, not the only aspect of context that influences use of these technologies. Communication is critically important within small groups, and most of the communication technologies listed in Table 43.1 are principally used by small groups, often just two people. Blogs and social networking sites are exceptions and are frequently used to communicate to a larger audience, perhaps a community of people with similar interests.

When small groups meet face-to-face, they may share information using meeting facilitation tools, a simple whiteboard, or a digital projector. When geographically distributed, small groups may share information using application-sharing technologies that allow everyone in the group to see and interact with the same information. Between meetings, they may store and access information managed by a document management system, shared folders, or a web-based team or project repository. Small groups may also use wikis to share information, but wikis are more widely known for their support of communities based on shared interests. Wikipedia is a prominent example of technological support for communities, not for small groups or organizations.

Small groups generally have little need for technologies that support coordination; they coordinate their activities by communicating and sharing information with one another. When geographically distributed, however, small groups may benefit from features of conferencing technologies that manage participation in a virtual meeting (session management) and limit participants' interactions

TABLE 43.1 Example Technologies Used in Collaborative Activity Categories

	Same Time	Different Time
Communication	• Telephone • Videoconferencing • Instant messaging • Texting	• E-mail • Voice mail • Blogs • Social networking sites
Information sharing	• Whiteboard • Application sharing • Digital projector • Meeting facilitation	• Document repositories • Websites • Team workspaces • Wikis
Coordination	• Floor control • Session management	• Workflow management • Computer-aided software engineering tools • Project management • Calendar scheduling

(floor control). Social protocols accomplish these functions in face-to-face meetings, but in online conferences, these features prevent unwanted guests and facilitate turn taking. Small groups and communities have little need for technologies that help coordinate their different-time collaborations, but coordination is the principal challenge facing organizations. They invest in technologies that coordinate the collaborative work involved in designing, producing, and delivering their products and services such as computer-aided software engineering (CASE) tools, workflow management systems, and project management tools.

People collaborate for many purposes in different contexts and employing diverse collaborative activities. CSCW encompasses all these purposes, and collaboration technologies may be employed in any online collaborative activities. Small groups may use collaboration technologies to stay connected with distant team members, present ideas to a remote audience, generate ideas and make decisions in a group meeting, or play an online game. Organizations may use collaboration technologies to coordinate all aspects of their business, including production, delivery, and maintenance of their products. Communities may use technologies to discover others with shared interest, collect information about their interest, and provide community services.

43.2.3 Research Methods

The challenge in CSCW is to understand collaboration and how technologies can support it. Gaining this understanding is accomplished through research methods acquired from other disciplines that study human behavior such as psychology, sociology, and anthropology. Experiments in laboratories are of greatest value when designed to shed light on enduring properties of human behavior. For example, the experimental method has provided insights into the influence of visual display properties on trust and empathy during videoconferences (Nguyen and Canny, 2007, 2009) and the costs and benefits of communication between two collaborating people (Dabbish and Kraut, 2003, 2004).

The experimental method is less fruitful when studying complex collaborative activities such as software development, medical operations, or emergency responses. A researcher cannot randomly assign people to teams or treatments, and these contexts cannot easily be recreated in a laboratory setting. Instead, observational methods are employed, borrowing heavily from ethnography. Observers study and record team behavior, learning what team members do and how and why they do it in specific contexts. For example, Jackson et al. (2012) investigated maintenance and repair of the information and communication infrastructure in Nambia; Benford et al. (2012) investigated traditional Irish music making in pubs; and Pine (2012) investigated the coordination of care in the labor and delivery unit of a hospital. Observational research may identify opportunities for technological interventions, capture changes in behaviors during technology adoption, and reveal the effects (both positive and negative) of an implemented technology.

Both experimental and observational methods are inadequate for studies of large-scale online collaboration such as the construction and maintenance of Wikipedia. Participants in these collaborations are often anonymous, or at least unknown to the researcher, posing an obstacle to direct observation or controlled experimentation. These collaborations are, however, often prolific, and the products and traces of their production are accessible online. Methods for mining, analyzing, and interpreting the results of these collaborations are providing interesting insights. For example, Keegan et al. (2012) employed exponential random graph models (see Robins et al., 2007) to analyze and compare the coauthorship networks in Wikipedia of articles about breaking news and articles about contemporary and historical events. They found that the emergent organization of authors and editors of Wikipedia articles is influenced by attributes of both the editors and the article content, and editor experience is among the strongest influences. In addition to analyzing collaboration networks, mathematical methods may be employed to analyze content. For example, Al-Ani et al. (2012) employed topic modeling analysis (see Blei et al., 2003) to investigate the evolution of the content of blogs written in Egypt during the Egyptian

revolution. By using mathematical models such as these, researchers can identify relationships in large-scale collaborations similar to those that ethnographers would find in smaller scale collaborations.

43.3 Impact on Practice

Collaborating with the support of computers is widespread today in small groups, organizations, and communities, and the practice of CSCW continues to accelerate. Despite obvious progress over the past 25 years, CSCW research offers some lessons, some warnings, and some advice for collaborators and for developers of collaboration technologies.

43.3.1 Grudin's Eight Challenges

In one of the most frequently cited articles in CSCW, Grudin (1994) listed eight challenges that continue to plague developers and users of collaboration technologies. These challenges are not technical problems; they arise from human psychology in social and organizational settings and may be avoided through thoughtful analysis of the collaborative context and careful design.

The first challenge is that users are reluctant to adopt a collaborative technology if the effort required outweighs the benefits they receive as individuals, regardless of the potential collective benefit. For example, employees have repeatedly resisted adopting time-tracking technologies despite their managers' belief that the information will yield greater overall work efficiency. Technologies that require more effort from a person should return a benefit to that person.

The second challenge is to achieve a critical mass of users. If some people involved in a collaboration decline to adopt a technology, the advantages of the technology for all other participants may be undermined. For example, a distributed group I observed using videoconferencing to support long-distance meetings abandoned the technology because one person was uncomfortable facing a camera.

The third challenge is to avoid interfering with complex and subtle social dynamics of a group. Our actions are guided by social conventions and awareness of people and priorities, awareness that computers generally do not share. Knowledge of the usage context may be required to design an application or to guide its adoption in a way that does not disrupt existing communication channels, create uncertainty about where to find information, or challenge existing authority structures.

The fourth challenge is to allow exceptions to standardized work practices. Technologies intended to coordinate work activities often incorporate and enforce models of the work processes and cannot easily accommodate deviations from these models. An important contribution of CSCW ethnographic studies (Suchman, 1983; Sachs, 1995) is the observation that handling exceptions and unanticipated events is normal behavior in the workplace, and strict adherence to standard processes is a rare exception.

The fifth challenge for technology designers is that the collaboration features of a technology must be readily accessible although they may be infrequently used. The challenge for the users of the technology is to understand how to use these potentially unfamiliar features while collaborating with other people. There is a risk that people may feel uncomfortable revealing to their friends or colleagues their lack of expertise with the technology.

The sixth challenge, as developer or user, is to evaluate the technology reliably. The methods developed for evaluating a single-user technology, such as walkthrough analysis or laboratory studies, are of limited value when assessing how well a team, organization, or community is supported by a technology. Users face the same challenge when choosing between technology alternatives. Evaluations of collaboration technologies generally take much longer to achieve a comparable level of reliability.

The seventh challenge is a breakdown in the intuitive decision-making process that normally guides product development and acquisition. These decisions are generally made by development or IT managers based on their informed intuitions regarding the strengths and weaknesses of alternatives.

Managers' expertise in an application domain may be a solid foundation for intuitive decision-making, but they are unlikely to have expertise in all the aspects of group dynamics that influence the success of a collaboration technology.

The eighth and final challenge is to manage the adoption of collaboration technologies. There is substantial risk of failure when a new collaboration technology is developed or acquired because of the pitfalls posed by the preceding seven challenges. Success requires that all the participants in a collaborative activity adopt the technology together, and this is unlikely to occur without careful planning.

43.3.2 Adoption of Collaboration Technologies

Grudin (1994) noted the challenge of managing adoption of collaboration technologies. The scope of this challenge and methods for addressing it depend on attributes of the collaboration context. For example, technologies intended to support small group, organizational, and community collaboration face very different challenges.

43.3.2.1 Adoption by Small Groups

Mark and Poltrock (2003, 2004) studied the adoption of desktop conferencing (sometimes called data conferencing) by geographically distributed teams in a large corporate setting. In this case, the technology was successfully adopted without a top–down management plan, but the diffusion process was slow and painful. Adoption was driven by users who recognized the benefits of the technology, demonstrated it to their coworkers, and helped each other learn to use it. Employees were often in one or more geographically distributed teams, and each such team constituted a social world. Information about the technology was communicated across social worlds, and people wanting to participate in a social world found that they needed the technology to be a successful contributor. The technology diffused rapidly across some parts of the company, but the managers of other parts considered this new technology to be a risk to network reliability and actively opposed its adoption. To function effectively, team members must uniformly adopt the technology, but people are members of multiple social worlds, and the active resistance of management in some social worlds created conflict and tensions. Eventually, the benefits of the technology were widely recognized, it was adopted by executive management, and resistance faded away, but the adoption process was long and painful for some individuals.

43.3.2.2 Adoption by Organizations

The primary challenge of organizational collaboration is the coordination of work activities. Workflow management systems, or product-focused tools with workflow management features, are often acquired for the purpose of coordinating the contributions of many distributed groups within an organization and sometimes across organizational boundaries. Acquisition and deployment of these systems are generally a substantial investment requiring top–down planning and integration with other tools and infrastructure. Unfortunately, these implementations are often unsuccessful (Bowers et al., 1995; Kingsbury, 1997) due to social and organizational factors that lead to adoption challenges.

Workflow management systems contain explicit representations of work processes and are intended to facilitate these processes by managing the transfer of work products from one person or group to another as tasks are completed. A promised benefit of these systems is that the defined work processes must be consistently followed, but the difficulty of defining stable work processes is a fundamental problem. Suchman (1983) asked members of an accounts payable organization to describe their processes, and she received a textbook explanation. When she observed their work, however, no single instance of their work followed the processes they had described. She distinguished between their plan (their documented process) and their procedures situated in the context of a particular process instance (Suchman, 1987). People engage in considerable problem-solving to ensure that the work complies with the expected results of the overall plan, but they accommodate the circumstances that are unique to each work instance.

Ishii and Ohkubo (1990) developed a workflow modeling and automation technology for office work and encountered this same problem. They successfully built a technology capable of managing the flow of work, but found that people did not consistently perform their work in accordance with the process they had described.

I participated in the design, deployment, and evaluation of several workflow management applications intended to support an engineering design organization. The organization employed a small staff of coordinators who acted as human workflow management engines; they collected the results of each task, delivered it to the next person or group, reminded people of incomplete tasks and deadlines, and kept track of each work instance. The workflow management applications were intended to perform much of this work, reducing the number of human coordinators required to manage the work. These coordinators were experts in the work processes, but nonetheless were unable to describe them accurately and completely.

A purported advantage of workflow management systems is the ease with which process models can be revised, achieving some degree of flexibility. Instead, the workflow applications that I helped deploy were inherently and unavoidably less flexible than the human-powered systems they replaced. Suppose the organization decided to revise a work process. A process facilitated by a human coordinator using e-mail and office documents can be changed by simply updating the process documentation and informing everyone about the revisions. The human coordinator would monitor the outcome, resolve any short-term problems, and propose additional revisions if any lasting problems are identified. But a workflow application is much more than a simple description of the process flow. Developing a workflow application requires modeling the data that will be managed in the workflow, defining the process rules, and developing the user interface required to view and edit the process-related data. It requires the same software development rigor as any other application development, and in this organization, all changes to software required thorough testing and release on a schedule coordinated with all other applications. If the revised processes create unexpected problems, there are no simple ways to make short-term adjustments, and further process revisions require another cycle of development and testing.

Even when processes remained stable, workflow management systems could not provide the flexibility offered by human coordinators. The workflow system sent e-mail messages to alert or remind people about tasks, and it provided lists of incomplete tasks. In contrast, coordinators alerted and reminded people in many ways, exploiting their knowledge of the individuals responsible for the tasks. An e-mail message was sufficient for some people, but coordinators knew who had an overflowing inbox and would be more receptive to a phone call or a personal visit. They knew when someone was on vacation and who was authorized as a substitute. To continue providing these services after the workflow management system was implemented, the coordinators continued to track all processes in spreadsheets, duplicating the information in the workflow system (Handel and Poltrock, 2011).

Achieving flexibility in workflow management applications remains an active area of research (Pesic and van der Aalst, 2006). Human coordinators could provide flexibility in many ways that exceeded the capacities of a workflow management system. Of course, human coordinators are expensive, and organizations may choose to adopt a workflow management system to avoid that cost, but these savings must be weighed against the costs of developing and maintaining a workflow management system.

43.3.2.3 Adoption by Communities

In striking contrast to the coordination demands of organizations, communities have little need for coordination technologies and primarily need tools for sharing information. An abundance of online social media services are aimed at addressing the needs of various communities. These include photograph (or other image) sharing sites, wikis devoted to topics of interest to specific communities, marketplaces where items can be bought and sold, and websites devoted to specific crafts, hobbies, or intellectual interests.

For the developer of such a technology, the first adoption challenge is to inform members of the target community about the opportunity offered by the technology. Early adopters may be found by

visiting places where community members may gather in the real world or through existing organizations that support the community. The second challenge is to persuade potential adopters that the technology offers a value greater than its cost. Many community services address the cost side of this challenge by offering their services for free. The third challenge is to attract additional members of the community and engage them in active use of the technology such that it becomes indispensable. Social media technologies often address this challenge by encouraging users to invite their friends, often using their e-mail address books or other lists of contacts. Of course, such a technology service must have some source of income, and it may solicit charitable giving from the community or advertise products of interest to that specific community. Consider, for example, the community of postage stamp collectors. This community has constructed an excellent summary of stamp collecting in Wikipedia, including links to other online sources. One of these sources (learnaboutstamps.com) is sponsored by the U.S. Postal Service and the American Philatelic Society, among other organizations. This society's own website invites charitable contributions to support the community and includes an online marketplace where its members can buy and sell stamps.

These examples illustrate the challenges that both developers and users may encounter with technologies intended to support collaboration within small groups, organizations, or communities. Note that all the challenges have their roots in human behavior, not in the limitations of technologies. Collaboration is a social activity, and social practices can be leveraged to achieve extraordinary success or become obstacles that impede technology adoption.

43.4 Research Issues

CSCW research can be roughly divided into two large categories, one focused on understanding collaboration and how technology influences it, and the other focused on the computer science challenges involved in supporting collaboration. Jacovi et al. (2006) presented empirical evidence for this categorization. They analyzed the citation graph of all 465 papers presented at CSCW conferences between 1986 (the first conference) and 2004. They identified eight clusters, of which the two largest correspond roughly to social science and computer science. The social science cluster included papers about theories and models, ethnography, collocated teams, organizational memory, awareness, and user studies such as studies of adoption. The third largest cluster included meeting/decision support, shared media spaces, and conferencing. A fourth cluster included papers on instant messaging, presence, and social spaces. Smaller clusters included papers on the use of computer tools in the workplace, groupware design and workspace awareness, management of computing and information systems, and video-mediated communication and shared visual spaces.

Convertino et al. (2006) analyzed the same 465 research papers, categorizing each paper by type of institutional affiliation, author's geographical location, its level of analysis (individual, group, or organization), type of contribution (theory, design, or evaluation), and type of collaboration function investigated (communication, coordination, or cooperation). About 80% of the papers were about small group collaboration and nearly all the rest had an organizational focus. Research on community collaboration emerged as an important theme after the years from 1986 to 2004 covered by these analyses. Most papers contributed to either design (corresponding roughly to the computer science cluster of Jacovi et al., 2006) or evaluation (corresponding to the social science cluster). Contributions to theory were frequent at the first three conferences (about 30% of papers) but then declined to fewer than 10%. Grudin and Poltrock (2012) attributed this decline to the departure of the Management Information System (MIS) community from the conference, a departure driven by decisions to archive ACM conference proceedings and establish high-quality standards and high rejection rates for conferences. In many research communities, including MIS, researchers may present their work in progress at conferences and reserve their highest quality work for publication in journals. Indeed, the MIS community continued its active research in group support systems (e.g., research in collaboration engineering such as Kolfschoten et al. 2006) and organizational collaboration in business settings (e.g., business process

management research). This research can be found in the *Proceedings of the Hawaii International Conference on Systems Science* and published in various Information Systems Journals.

This chapter does not address the challenging computer science issues in CSCW. It focuses, instead, on research seeking to understand collaboration and how technology influences it when collaboration takes place in small groups, organizations, and communities.

43.4.1 Small Group Collaboration—Videoconferencing

About 80% of the research presented at CSCW conferences between 1986 and 2004 explored aspects of small group collaboration (Convertino et al., 2006). Researchers have investigated ways to support small groups in face-to-face meetings and when they are geographically distributed. They have explored meeting or decision-support technologies, communication technologies, and ways to share information. This chapter focuses on videoconferencing, a form of small group communication that has been intensively studied in many ways over many decades.

Videoconferencing supports integrated and synchronized visual and audio communication. It is an old technology that has become dramatically more usable and affordable in recent years. In 1878, du Maurier created a cartoon of a Telephonoscope that would transmit both sound and images bidirectionally. In 1927, when Herbert Hoover was US Secretary of Commerce, he used a videoconference system in Washington to communicate with AT&T President Walter Gifford in New York. This, of course, was a prototype system, but AT&T continued pursuing the idea, developed the Picturephone in the 1950s, and launched the commercial Picturephone product in 1970. The technology was a commercial failure, but telephone companies continued to research and develop videoconferencing technology, and some of their research is included in the CSCW literature. Nonetheless, adoption of videoconferencing was surprisingly slow. Throughout the twentieth century, it was little used outside research labs and in some government and industry settings that required long-distance collaboration.

Improvements in videoconferencing and network technology have dramatically enhanced its quality and reduced its cost. This long history of improvements, including integration of videoconferencing with computers and their networks, has generated repeated resurgences of interest in videoconference systems. Engelbart and English (1968) demonstrated videoconferencing, including overlays of video and data, in their groundbreaking research exploring how computers could augment human intellect. Despite this steady stream of improvements, adoption of videoconferencing remained slow until recently. Today, many executives have personal videoconference systems on their desks, consumers use Skype's features to communicate with friends and family, and cameras are built into computers and mobile phones. The ability to communicate both visually and auditorially seems intuitively appealing, and its slow adoption despite improved performance and declining cost posed a puzzle that attracted many researchers.

At the second CSCW conference, Egido (1988) reviewed reasons for the failures of videoconferencing. She noted that forecasts in the early 1970s predicted that 85% of all business meetings would be electronically mediated by the end of that decade. But, when her paper was written in 1987, only about 100 videoconferencing facilities existed worldwide, and many of those were located in the offices of teleconferencing vendors and telecommunication companies. Egido argued that two factors were responsible for the low rate of videoconferencing adoption. The first factor was the inadequacy of needs-assessment methodologies, which were largely based on surveys at that time, with the consequence that technologies were not designed appropriately for the contexts in which they would be used. The second and closely related factor was the portrayal of videoconferencing as a direct replacement for face-to-face meetings. It does not provide the same opportunities for interpersonal interactions that occur in business meetings, and many years of research have found no decrease in face-to-face meetings when videoconferencing is available. Egido concluded that videoconferencing may be an attractive (if expensive) communication option in many situations, and research should focus on understanding communication tasks in the office environment and how such a technology could best support it.

At the same conference, Robert Root (1988) followed Egido's advice and proposed a system called CRUISER based on a thoughtful analysis of office communication patterns. Root observed the importance of frequent, low-cost face-to-face interactions in which both technical and personal information can be exchanged quickly and easily. He designed CRUISER to support social interaction in office environments that are geographically distributed, providing easy, convenient access to other people regardless of their physical location. Its users were able to stroll (metaphorically) down a virtual office hall, peek into virtual offices via videoconferencing, and stop to chat for a while if the office occupant was available. Note that this research involves an analysis of a social context, identification of the technology requirements to support collaboration in this context, and a proposed system intended to address these requirements. There is, of course, a big gap between a technology proposal such as this one and the development of a successful system that meets all the requirements and integrates seamlessly into the social environment.

Root and his colleagues implemented and evaluated CRUISER in a research and development laboratory (Fish et al., 1992). CRUISER was essentially a videoconferencing system with full-duplex audio, but it included three novel ways to initiate conversations: (1) *cruises* opened an immediate videoconference connection to a called party that timed out after 3 s unless the recipient explicitly accepted it, (2) *autocruises* initiated 3 s calls between selected users at random times that were extended only if both parties accepted it, and (3) *glances* opened a one-way video-only connection to the recipient's office that lasted only 1 s. Observations of how people used this system were enlightening about the challenges facing videoconferencing developers. CRUISER metrics indicated that the cruise feature was used much more than a glance, and autocruises were rarely used. Videoconferences initiated by the cruise feature were short, rarely lasting more than a few minutes, and were primarily used to schedule a face-to-face meeting or for status reporting. People frequently used it to see whether someone was present and available, and then arranged to visit them. But the sudden onset of the cruise or glance connection was perceived as intrusive, disruptive, and an invasion of privacy. Its developers had hoped to recreate the opportunities for informal social interaction that occur when walking between offices, but CRUISER's interaction methods were very different from the methods that people use when meeting one another face-to-face.

CRUISER was among the first of many systems developed to explore novel ways to establish videoconferences quickly and easily while respecting privacy (Cool et al., 1992; Tang et al., 1994). Researchers reasoned that persistent dissatisfaction with videoconferencing could, in part, be due to the clumsy process of starting and ending contact, a process that Tang (2007) termed *contact negotiation*. Members of a collocated team can easily see when other team members are busy or available, and they can easily negotiate contact with one another. Dourish and Bly (1992) developed Portholes to provide similar awareness of availability to distributed teams. Portholes displayed thumbnail images of team members from cameras in their offices, offering a quick and current view of who was present and available. Clicking on one of the thumbnail images in later versions of Portholes brought up a menu of communication options including videoconferencing (Lee et al., 1997). Systems such as Portholes facilitate awareness and contact negotiation but again raise concerns about privacy. Many people feel uncomfortable with the idea of being continuously visible via a camera image, even though they may be continuously visible to others in an open office environment. Tang (2007) reviewed research investigating alternative approaches to negotiating contact, concluding that the essential cognitive and social cues could be conveyed via text and icons instead of attempting to recreate sensory cues through video. His research demonstrates an approach that may successfully avoid the experience of an invasion of privacy.

While some researchers focused on simplifying contact negotiation, others questioned the benefits provided by video. The book *Video-Mediated Communication* (Finn et al., 1997) included 25 papers by noted researchers in the field exploring these benefits. To a great extent, these papers confirmed the findings of earlier studies that the addition of video to audio communication does not improve collaborative problem-solving. Furthermore, many people have stated informally that they do not want to see or be seen by the person with whom they are speaking while discussing business. This has been a

disappointment to the telecommunication and network companies that hoped widespread adoption of videoconferencing by US industry would drive an increase in demand for bandwidth.

More recent research suggests that there are benefits of adding video to an audio communication channel, but the benefit is not better collaborative problem-solving. Williams (1997) found that video led to improved conflict resolution in stressful communication conditions, such as when two people with different native languages must negotiate in English. In three-way videoconferences (between three different locations), video showing both remote participants simultaneously (spatial video) helped people keep track of their three-way conversations and yielded higher quality conversations in the judgment of the participants (Inkpen et al., 2010). Video also provides a way that people can collaborate on a physical task, but in these situations the cameras are focused on the task and not the people (Kraut et al., 1996). Indeed, in some situations video can be a distraction and impair performance. Pan et al. (2009) presented English clips to Chinese students and tested their comprehension. The students achieved better comprehension with audio alone than with audio plus video.

Although the benefits of adding video to an audio conference are difficult to quantify, many people clearly enjoy the experience more. Even the studies that found no benefits (Finn et al., 1997) reported that participants liked seeing one another and believed that they had achieved a better solution, despite the objective evidence that they had not. This observation has led some researchers to explore emotional or affective consequences of videoconferencing.

One reason that people meet face to face is to establish a relationship and level of trust that will sustain their collaboration when geographically distributed. If videoconferencing is intended to replace face-to-face meetings, then its support for developing trust is important. Bos et al. (2002) studied the effects of four computer-mediated communication channels on trust development: face-to-face, audio, audio plus video, and text chat. They measured trust between three people using a game that poses a social dilemma. To cooperate, they must trust one another, and consequently their success in the game can be considered a measure of the trust within the group. Groups in the face-to-face condition began cooperating quickly; groups in the text chat condition never learned to cooperate; and both the audio groups and the audio plus video groups eventually learned to cooperate, but continued to experience defections throughout the game. These results suggest that communication mediated by technology does not support an awareness of the presence of others as effectively as face-to-face meetings.

The failure of videoconferencing to support development of trust posed a challenge to researchers in this field. Nguyen and Canny (2005, 2007) took up this challenge and investigated whether it was a social consequence of the breakdown of eye gaze awareness, which is disrupted in videoconferencing because camera lenses are not located where the eyes are displayed. They developed a group videoconferencing system that provides spatially faithful eye gaze awareness and studied the development of trust in three conditions: face-to-face meetings, their spatially faithful videoconference system, and a similar system with conventional nonfaithful displays. Like Bos et al. (2002), they indirectly measured trust via performance in a game that poses a social dilemma. They found that game performance and thus trust were essentially equal when people met face-to-face or when using the spatially faithful videoconference system, but was lower and more fragile when using the conventional system. These results suggest that eye gaze awareness and mutual gaze may contribute to the development of trust.

Many studies have found that face-to-face encounters are superior to videoconferences in establishing trust or feeling that a conversation is natural. Reconsidering the implications of their own research, Nguyen and Canny (2009) noted that even studies with mutual gaze awareness had found substantial and consistent differences between face-to-face interactions and videoconferencing. They hypothesized that eye gaze awareness was not the sole reason that they had found equal development of trust in face-to-face and video conditions. Instead, they proposed that video framing had played an important but unnoticed role. Videoconferencing equipment is usually configured to show only the heads or the heads and shoulders of participants, and most commercial videoconferencing systems (including laptop computers) are similarly configured. Nguyen and Canny's system, however, was configured to display the entire upper body at life size. In typical videoconferences, the main

nonverbal channels of communication are facial expression and gaze, but their system had added three additional nonverbal communication channels: posture, gesture, and proxemics.

Nguyen and Canny (2009) conducted an experiment in which two participants talked for 20 min in one of three conditions: (1) face-to-face seated across a table from one another, (2) in a videoconference with a life size view of the other participant's upper body, or (3) in a videoconference with the same equipment but masked so that they could see only the face of the other participant. Near the end of the experiment, one of the two participants was asked to assist the experimenter by entering the room with the other participant and pretend to accidentally drop some pens. Nguyen and Canny reasoned that the other participant would be more likely to help pick up the pens if the two participants had indeed established empathy during their 20 min conversation. The experimenter measured whether the other participant helped pick up the pens and the time until the participant initiated that behavior. There were no significant differences in measures of empathy or the pen-drop experiment between the face-to-face meeting and the videoconference showing the whole upper body, but the two videoconferencing conditions were strikingly different. When participants viewed only the face, their ratings of empathy were lower; they were less likely to help pick up pens, and they were much slower to pick up pens. These results are strong evidence that a videoconference showing the whole upper body at life size will yield better nonverbal communication and more effectively support development of empathy than a videoconference showing only the face.

Today, video cameras are integrated in laptop computers and mobile telephones, and videoconferencing services that use these cameras are freely available. Although videoconferencing is freely available, its adoption remains much lower than other prominent communication technologies such as telephones, e-mail, and text messages. Researchers have identified key barriers to adoption and pointed the way to solutions. Nguyen and Canny's results tell us that videoconferences will be competitive with face-to-face meetings if they display the whole upper body and achieve good eye gaze awareness, and high-end or immersive commercial systems have adopted this framing recommendation. Contact negotiation in most commercial systems is modeled on a telephone calling interface, but researchers have evaluated other approaches that offer promising improvements in the videoconferencing experience.

43.4.2 Organizational Collaboration

Organizational collaboration occurs when two or more groups work together, requiring coordination of their mutual efforts. As described earlier, workflow management technologies provide coordination mechanisms intended to support organizational collaboration. Workflow management systems typically contain an explicit, editable model of work processes, and they pass work artifacts and assignments from person to person (or group to group) in accordance with this model.

Although workflow management is widely used in some industries, its value has been controversial in the CSCW research community. During the early years of CSCW, some researchers were optimistic about the potential for aiding collaboration through development and implementation of formal models that both described and guided the work. Winograd and Flores' (1986) explorations of the conversation-for-action analysis method inspired novel approaches for modeling work processes and using these models to coordinate work (Medina-Mora et al., 1992; De Michelis and Grasso, 1994). Suchman (1994) criticized these technologies on two grounds. First, the technologies embody a categorization scheme and impose this scheme on its user community, displacing their own preexisting categories for describing their work. Second, a workflow system that mediates all work activities amounts to an oppressive disciplinary regime and is politically repugnant. Winograd (1994) responded to these criticisms, explaining that the categorization schemes used in workflow management are not intended to serve as models of language but as structures that support unambiguous communication across organizational boundaries, and that workflow systems need not be oppressive. This debate essentially ended contributions to workflow management research within the CSCW community, with

the exception of approaches intended to increase flexibility and give greater control of the work process to the user community (e.g., Dourish et al., 1996).

Research in organizational collaboration is principally found in management journals and conference proceedings, but some threads continue to find an audience within the CSCW community. Researchers have explored the flow of information within organizations, investigating properties of organizational memory (Ackerman and Halverson, 1998) and the role of social network systems in organizational acculturation, which is essential to successful organizational collaboration (Thom-Santelli et al., 2011). Balka and Wagner (2006) studied how technology is appropriated within organizations, focusing on the configurations required to make new technologies work successfully. One generally thinks about configuring the technology itself, but they noted that new technologies may require configuring organizational relations, space and technology relations, and the connectivity of people, places, and materials. Similarly, Lee et al. (2006) proposed expanding the concept of cyberinfrastructure to include the associated human infrastructure (people, organizations, and networks) as a way to bring into focus some of the factors that are critical to a successful cyberinfrastructure program.

Recent work in organizational collaboration has focused on domains or settings of special interest such as insurance, hospitals, and nonprofit enterprises. Painter (2002) studied the adoption of a new electronic claim file system in a health insurance program and its effects on collaboration. Abraham and Reddy (2008) studied coordination between clinical and nonclinical staff in the patient transfer process of a hospital, focusing on failures of information sharing and the reasons for these failures. Le Dantec and Edwards (2008) compared two nonprofit homeless outreach centers and found that differences in their organizational structures and composition were tightly coupled to differences in their use of information and communication technologies. Many workers in these settings are volunteers who do not receive much training in organizational processes or its technologies, offering both an opportunity and a challenge for coordinating technologies such as workflow management. Stoll et al. (2010) examined coordination across multiple nonprofit organizations seeking to help the victims of human trafficking. Their work highlights structural, technological, and organizational factors that challenge nonprofit organizations seeking to employ technologies that are widely used in the for-profit world.

43.4.3 Community Collaboration

In recent years, the CSCW research community has grown increasingly interested in collaborations that occur within communities, especially online communities. The participants in these collaborations are not members of the same teams or organizations. Often, they do not know one another. Nonetheless, online community collaborations have yielded impressive results, as exemplified by Wikipedia. Researchers seek to understand who participates in these communities, why they do it, how they become informed members of the communities, how their collaborations are structured or organized, and how their participation evolves over time.

Not surprisingly, the most frequently studied online community collaboration is the production and maintenance of the Wikipedia online encyclopedia. This research is important because the encyclopedia is massive and widely used. The Wikipedia system indirectly supports this research by saving all contributions by authors and editors online where researchers can readily access it.

Bryant et al. (2005) were among the first to study contributions to Wikipedia, and the first of several to focus on how people became active editors of Wikipedia. They interviewed nine people who frequently edit Wikipedia pages. They described their results using activity theory in which the building blocks are objects, subjects, community, division of labor, tools, and rules. They described the evolution from a novice editor to an expert Wikipedian as a transformation in each of these six areas. For example, editors develop a feeling of membership in a community while learning the community's rules and tools.

Of course, most users of Wikipedia only read articles and never contribute to an article. Antin and Cheshire (2010) ask why people contribute to Wikipedia when they could gain its benefits by just reading it without the work of writing and editing it, and then suggest that readers would also like to contribute

but do not because they do not know enough about the system to feel ready to do it. They argue that reading is a form of legitimate peripheral participation, a category of behavior that provides a pathway to learn about the Wikipedia community and its environment. This is not, however, the only reason that people choose not to contribute. A survey of more than 40,000 users of Wikipedia explored reasons for not contributing, focusing on why so few women (less than 15%) are contributors (Collier and Bear, 2012). They found that women were less likely than men to feel confident in their expertise and the value of their contribution, they were more likely to feel uncomfortable with the high level of conflict involved in the editing process, and they were less likely to feel comfortable editing another person's work.

The distribution of contributions to Wikipedia follows a power law, with most people making very few edits. Antin et al. (2012) studied the factors that distinguish between people who make many edits and those who make few edits. They found that early diversification into multiple kinds of editing activities is strongly predictive of more editing behaviors later, people continue to engage in the same kinds of activity patterns over time, and early diverse editing behaviors are associated with later organizational and administrative behaviors.

Contributors to Wikipedia interact not only with the content but also with one another. Choi et al. (2010) studied socialization of new members in WikiProjects, which are topic-centric subgroups of Wikipedia contributors that improve coverage in a particular domain. They studied the messages written to newcomers by existing project members and identified types of socialization tactics. Using correlational analyses, they found that more socialization messages were associated with more editing behavior by the newcomers. They performed trace ethnography, a method that generates a rich account of interactions by combining a fine-grained analysis of automatically recorded editing traces with an ethnographically derived understanding of the sources of these traces.

Millions of people rely on Wikipedia as a source of information, and the quality of its content has been widely discussed. Researchers have explored how this high quality is achieved and how attempts to undermine its content, such as vandalism, are thwarted. Arazy and Nov (2010) found that communication and coordination between contributors increased quality and that editors who contribute to many topics in Wikipedia yield higher quality. Geiger and Ribes (2010) described the work involved in countering acts of vandalism in Wikipedia as an instance of distributed cognition in which the task is distributed across people and software tools. Keegan and Gergle (2010) studied the emergence of a new information-control role they call one-sided gatekeeping. They found that elite editors of the *In The News* section of Wikipedia were able to block inappropriate news items effectively, acting as gatekeepers, but their gatekeeping was one-sided because they were not more effective at promoting a proposed news item.

This research illustrates the questions and approaches asked about participants in online communities. Studies of Wikipedia have focused on contributors to its contents more than readers of the content, viewing the contributors as the most active members of the communities. The primary questions involve who is contributing, why some contribute more than others, and how content quality is achieved. Research methods include interviews and surveys, but new methods have emerged that integrate these traditional methods with large-scale statistical analyses of online data. The understanding that emerges from this research may suggest tools and methods for improved support to large-scale collaborations.

43.5 Summary

This chapter has selectively reviewed concepts and principles in the area of CSCW, focusing on research that contributes to our understanding of how people collaborate and the effects of technology on their collaboration. Context strongly influences how people collaborate, and categorization models describe some of these influences by categorizing who collaborates (groups, organizations, and communities), where they collaborate (same place or different places), and when they collaborate (same time or different times).

Our understanding of collaboration has implications for both developers and users of collaboration technologies. Developers must avoid well-established challenges that often befall collaboration technologies, and they should adopt potentially unfamiliar methods for establishing requirements and evaluating collaboration technologies. Technology adoption is especially challenging, because it often requires that all collaborators use the same technology, but this same factor may cause adoption to be extraordinarily rapid once critical mass is achieved.

Our evolving understanding of collaboration is illustrated with reviews of research on three prominent topics pertaining to small group, organizational, and community collaboration. Videoconferencing is of special interest because of its long history, wide appeal, yet remarkably slow adoption rate. Although the cost has plummeted and quality has risen, videoconferencing has not achieved its predicted popularity. Research suggests that the user interface is the principle obstacle to adoption. Contact negotiation remains awkward, and most videoconference devices fail to display important communicative behaviors. New technologies designed to benefit from these lessons may find greater success in the marketplace.

Workflow management is a prominent example of support for organizational collaboration, but the CSCW research community has been highly critical of both the practical value and social impact of this technology. More recent research has focused on the organizational collaboration challenges faced in domains of special interest such as health care and charities.

Interest in community collaboration, especially online communities, is growing. Online communities offer an attractive laboratory for studying collaboration because interaction data are saved automatically and vast quantities of data are available. Recent studies of Wikipedia reveal who participates, why, and how in the construction and maintenance of this online encyclopedia.

The CSCW field continues to evolve in response to changes in technologies, changes in ways people collaborate using technologies, and changes in the population of users. In its infancy, CSCW was constrained to studies of the workplace because few people had access to computers outside the workplace and networks were primitive. Today, mobile phones have greater computing power than those early personal computers, computing technologies are inexpensive, networks are ubiquitous, and information services are readily available. Other technology trends such as adoption of touch screens, tablet computers, and ubiquitous computing in the home, in the workplace, and in vehicles are all likely to influence how, where, and when people collaborate. Ongoing changes in technologies, usage contexts, and usage populations will pose new research questions and opportunities. For example, will the lessons learned about collaboration in the workplace prove applicable when children are collaborating in elementary schools? How will the ability to communicate and share information affect the lives of people living in poor rural areas? Researchers have been exploring collaboration among friends and within families, and this area of research will grow as people of all ages and incomes discover that collaboration technologies are both affordable and easy to use. Continuous communication availability may strengthen bonds within extended families, but it may also stress existing social norms. Access to shared information may empower people who have few economic resources, but the impacts on existing power and social structures may be unsettling.

Glossary

Awareness: Perception of relevant aspects of a communication context such as another person's availability for interaction or where another person is looking (eye gaze awareness).

Contact negotiation: The process of starting and ending contact in technology-mediated communication such as telephones and videoconferences.

Desktop conferencing: A category of technology that supports synchronous collaboration. All participants in a conferencing session see the same display with real-time updates, and some versions allow two or more people to interact with a display simultaneously.

Ethnography: A qualitative research approach for investigating what people do and how and why they do it. The data may include participant observation, field notes, interviews, surveys, and the work products of the people who are studied.

Legitimate peripheral participation: A theory describing how new members of a community are integrated into the community. Newcomers engage in simple, low-risk tasks that contribute to community goals.

Social world: A social world is a collection of people who have shared commitments to certain activities, share resources to achieve their goals, and build shared views by appropriate methods. Any type of collective unit can be a social world, including groups, organizations, and communities.

Workflow management: Coordination of sequences of work activities, assigning tasks to individuals, monitoring task progress, and, when a task is completed, forwarding relevant results to the person responsible for the next task. A workflow management system contains explicit models of the task sequences that comprise a work process and automatically manages the flow of work.

Further Information

CSCW research is presented and published in the proceedings of the annual *ACM Conference on Computer Supported Cooperative Work* (*CSCW*), the biannual *ACM International Conference on Supporting Group Work* (*GROUP*), the biannual *European Conference on Computer Supported Cooperative Work* (*ECSCW*), the *International Conference on Collaboration Technologies* (*CollabTech*), the *International Conference on Collaborative Computing* (*CollaborateCom*), and *Collaborative Technologies and Systems* (*CTS*). The principal journal in this field is *Computer Supported Cooperative Work: The Journal of Collaborative Computing*, published by Springer.

Influential early papers in the CSCW field can be found in Greif (1988) and Baecker (1993). Recent reviews include Olson and Olson (2011) and Grudin and Poltrock (2012).

44.1 Introduction

Fueled by a combination of decreasing costs and increasing capabilities, information technology (IT) has penetrated almost every successful workplace. Organizations have long focused on supporting the individual needs of their workers by offering applications such as word processors, spreadsheets, and database systems. However, with the advent of cost-effective communication technologies and ubiquitous Internet access, workplaces have become connected. As a result, the use of IT has shifted over the past 20 years from supporting pure computation activities toward coordination and collaboration activities within and between organizations. IT has become the essential vehicle for mediating interpersonal and group communication. As such, the nature and appearance of IT have changed accordingly. Information systems have taken the shape of socio-technical networks that are designed specifically to make information workers more effective at their jobs by means of making problem-solving and decision-making tasks more collaborative.

Collaboration technologies have enabled people to work together by sending, receiving, storing, retrieving, and co-creating information. This type of IT overcomes traditional collaboration constraints such as time, space, and hierarchy (Coleman and Levine, 2008; Lewin and Stephens, 1993). Although IT is often seen as an enabling technology, it can also be considered a *requirement* for effective organizational coordination and collaboration. Organizational work is increasingly becoming a group effort that requires flexibility and adaptiveness (Bunker and Alban, 2006; Ellinger, 2000; Hardy et al., 2005; Malone and Crowston, 1990; Tjosvold, 1988). Fundamentally, collaboration and coordination are the essential ingredients of organizational life: organizations form because people have to work together to create value that they cannot produce by themselves (Mintzberg, 1983). As coordination and collaboration require extensive information exchange, well-designed and usable systems are necessary to support the interdependencies between the actors in teams and organizations. Therefore, organizations require collaboration technologies that are capable of disseminating information fast, economically, reliably, and securely (Corbitt et al., 2000; Nunamaker et al., 2001).

This chapter addresses how organizations can enable teams to be more productive with collaboration technology. We first present a classification of the different types of collaboration technologies that organizations can use. Then, we introduce a model of team processes that describes the fundamental patterns of collaboration that teams can engage in, regardless of whether they use collaborative software applications or not. These patterns include *Generate, Converge, Organize, Evaluate,* and *Build consensus*. We describe key findings from past research, especially in the area of group support systems (GSSs), to illustrate how collaboration technology supports different types of team work in each of the five patterns. Next, we move from the team level to the organizational level where we discuss and illustrate the impact and added value of collaboration technology in an organization as a whole. We conclude this chapter by outlining three key future directions for collaboration technology research and practice.

44.2 Classification of Collaboration Technologies

This section examines the different types of collaboration technologies that are currently available. What began as an area with a few dozen professional applications in the early 1980s has grown to an industry for thousands of different systems, ranging from simple group texting apps to integrated work environments where teams communicate, deliberate, co-create, and store electronic artifacts (e.g., documents, models, and audio files). Taking a closer look at the typical capabilities that various collaboration technologies afford, Mittleman and colleagues classified them under four main categories according to their most fundamental capabilities: (1) jointly authored pages, (2) streaming tools, (3) information access tools, and (4) aggregated systems (Mittleman et al., 2009). The fourth category is for technologies that must integrate a mix of tools from the first three categories and optimize them to support work practices that cannot be achieved with a single technology. Each of these main categories can be subdivided into a number of subcategories based on the functions they are optimized to support. The complete classification scheme is presented in Table 44.1. Next, we discuss each of these categories in more detail.

44.2.1 Jointly Authored Pages

The most fundamental capability for all technologies in the jointly authored pages category is a digital page, defined as a single window to which multiple participants can contribute, often simultaneously. The pages might be able to represent text, graphics, numbers, or other digital objects. However, regardless of content, any contribution made by a participant will generally appear on the screens of the other participants who view the same page. A given technology based on jointly authored pages may provide a single page or multiple pages. Sometimes these tools allow for the creation of hierarchies or networks of pages. Jointly authored pages are the basis for several subcategories of collaboration technology including conversation tools, shared editors, group dynamics tools, and polling tools.

TABLE 44.1 Classification Scheme of Collaboration Technologies

Categories	Description
Jointly authored pages	*Technologies that provide one or more windows that multiple users may view, and to which multiple users may contribute, usually simultaneously*
Conversation tools	Optimized to support dialog among group members
Shared editors	Optimized for the joint production of deliverables like documents, spreadsheets, or graphics
Group dynamics tools	Optimized for creating, sustaining, or changing patterns of collaboration among people, making joint effort toward a goal (e.g., idea generation, idea clarification, idea evaluation, idea organization, and consensus building)
Polling tools	Optimized for gathering, aggregating, and understanding judgments, opinions, and information from multiple people
Streaming technologies	*Technologies that provide a continuous feed of changing data*
Desktop/application sharing	Optimized for remote viewing and/or control of the computers of other group members
Audio conferencing	Optimized for transmission and receipt of sounds
Video conferencing	Optimized for transmission and receipt of dynamic images
Information access tools	*Technologies that provide group members with ways to store, share, find, and classify data objects*
Shared file repositories	Provide group members with ways to store and share digital files
Social tagging systems	Provide means to affix keyword tags to digital objects so that users can find objects of interest and find others with similar interests
Search engines	Provide means to retrieve relevant digital objects from among vast stores of objects based on search criteria
Syndication tools	Provide notification of when new contributions of interest have been added to pages or repositories
Aggregated systems	Technologies that combine other technologies and tailor them to support a specific kind of task

Conversation tools are those primarily optimized to support dialog among group members. E-mail is a widely used conversation tool as well as short message service (SMS) (i.e., cell phone text messaging) that has become a ubiquitous application. According to the International Telecommunication Union, 6.1 trillion text messages were sent in 2010 (ITU, 2010). Other conversation tools include instant messaging, chat rooms, and blogs or threaded discussions. Instant messaging and chat rooms provide users with a single shared page to which they can make contributions to a chronologically ordered list. Participants may not move, edit, or delete their contributions. Instant messaging and chat rooms differ from one another only in their access and alert mechanisms. With instant messaging, an individual receives a pop-up invitation that another individual wishes to hold a conversation, while with chat rooms an individual browses to a website to find and join a conversation. Blogs (otherwise known as web logs) and threaded discussion tools are optimized for less-synchronous conversations. Users make a contribution, then come back later to see how others may have responded. Blogs and threaded discussions are typically persistent (i.e., their content remains even when users are not contributing), whereas chat rooms and instant messaging are usually ephemeral (i.e., when the last person exits a session, the session content disappears).

Shared editor tools are typically a jointly authored page optimized for the creation of a certain kind of deliverable by multiple authors. The content and affordances of these tools often match those of single-user office suite tools (e.g., word processing or spreadsheets). However, they are enhanced to accept

contributions and editing by multiple simultaneous users. A wiki (the Hawaiian word for "fast") is another example of joint document authoring. Wikis are simple web pages that can be created directly through a web browser by any authorized user without the use of offline web development tools.

Group dynamics tools are optimized for creating, sustaining, or changing patterns of collaboration among individuals making a joint effort toward a goal. The patterns these tools support include generating ideas, establishing shared understanding of them, converging on those worth more attention, organizing and evaluating ideas, and building consensus (Briggs et al., 2006). These tools are often implemented as multiple layers of jointly authored pages such that each contribution on a given page may serve as a hyperlink to a subpage. The affordances of such tools are typically easily configurable, so at any given moment a group leader can provide team members with the features they need (e.g., view, add, and move) while blocking features they should not be using (e.g., edit and delete).

Polling tools are a special class of jointly authored pages, optimized for gathering, aggregating, and understanding judgments or opinions from multiple people. At a minimum, the shared pages of a polling tool must offer a structure of one or more ballot items, a way for users to record votes, and a way to display results. Polling tools may offer rating, ranking, allocating, or categorizing evaluation methods and may also support the gathering of text-based responses to ballot items.

44.2.2 Streaming Technologies

The core capability of all tools in the streaming technologies category is a continuous feed of dynamic data. Desktop sharing, application sharing, and audio/video conferencing are common examples of streaming technologies.

Desktop and application sharing tools allow the events displayed on one computer to be seen on the screens of other computers. With some application sharing tools, members may use their own mouse and keyboard to control the remotely viewed computer. This type of collaboration technology is often used in distributed training or support settings.

Audio conferencing tools provide a continuous channel for multiple users to send and receive sound while *video conferencing tools* allow users to send and receive sound and moving images. Typically all users may receive contributions in both types of tools. Systems may, however, vary in the mechanisms they provide for alerts and access control as well as by the degree to which affordances can be configured and controlled by a leader.

44.2.3 Information Access Technologies

Information access technologies provide ways to store, share, classify, and find data and information objects. Key examples in this category include shared file repositories, social tagging, search engines, and syndication tools.

Shared file repositories provide mechanisms for group members to store digital files where others in the group can access them. Some systems also provide version control mechanisms such as check-out/check-in capabilities and version backups.

Social tagging allows users to affix keyword tags to digital objects in a shared repository. For example, the website del.icio.us allows users to store and tag their favorite web links (i.e., bookmarks) online so that they can access them from any computer. Users are not only able to access their own bookmarks by keyword, but bookmarks posted and tagged by others as well. More significantly, users can find other users who share an interest in the same content. Social tagging systems allow for the rapid formation of communities of interest and communities of practice around the content of the data repository. The data in a social tagging repository are said to be organized in a folksonomy, an organization scheme that emerges organically from the many ways that users think of and tag contributions, rather than in an expert-defined taxonomy.

Search engines use search criteria provided by team members to retrieve digital objects from among vast stores of such objects (e.g., the World Wide Web, the blogosphere, and digital libraries). Search criteria may include content, tags, and other attributes of the objects in the search space. Some search engines interpret the semantic content of the search request to find related content that is not an exact match for the search criteria.

Syndication tools allow a user to receive a notification when new contributions are made to pages or repositories they find interesting (e.g., blogs, wikis, and social networks). Users subscribe to receive update alerts from a feed on a syndicated site. Every time the site changes, the feed broadcasts an alert message to all its subscribers. Users view alerts using software called an aggregator. Any time a user opens their aggregator, they see which of their subscription sites has new contributions. Therefore, users do not need to scan all contents to discover new contributions.

44.2.4 Aggregated Technologies

Aggregated technologies integrate several technologies from the other three categories and optimize them to support tasks and processes that cannot be executed using a single technology. Aggregated technologies deliver value that could also be achieved with a collection of stand-alone tools. There are many examples of aggregated technologies, among them virtual workspaces, web conferencing systems, social networking systems, and GSS. Virtual workspaces often combine document repositories, team calendars, conversation tools, and other technologies that make it easier for team members to execute coordinated efforts (e.g., SharePoint). Remote presentation or web conferencing systems often combine application sharing and audio streams with document repositories and polling tools optimized to support one-to-many broadcast of presentations, with some ability for the audience to provide feedback to the presenter (e.g., WebEx or SameTime). Social networking systems (e.g., MySpace, Facebook, or Flickr) combine social tagging with elements of wikis, blogs, other shared page tools, and a search engine so that users can find and communicate with their acquaintances as well as establish new relationships based on mutual friends or mutual interests. Thus, aggregated technologies may combine any mix of shared-page, streaming, and information access technologies to support a particular purpose.

GSSs integrate collections of group dynamics tools to move groups seamlessly through a series of activities toward a goal, for example, by generating ideas in one tool, organizing them in another, and evaluating them in yet another (e.g., ThinkTank or MeetingWorks). Specifically, a GSS is a collection of collaborative meeting tools designed to improve creative co-creation, problem solving, and decision making by teams (de Vreede et al., 2003). A GSS is typically implemented on a collection of personal computers that are connected through a (wireless) LAN or through the Internet. Sometimes, participants work in meeting rooms especially designed for electronically supported meetings. Other times, the participants simply move laptop computers into a standard meeting room and begin their work. Still other times, participants used lean GSS applications asynchronously, especially since the emergence of web-based GSS applications in the mid-2000s.

A GSS permits all participants to contribute at once by typing their ideas into the system. The system immediately makes all contributions available to the other participants on their screens. Nobody has to wait for a turn to speak, so people do not forget what they want to say while waiting for the floor. People do not forget what has been said, because there is an electronic record of the conversation on their screens. GSSs also allow a team to enter ideas anonymously. During the generation phase of creativity, it is often useful to get every idea on the table, but people often hold back unconventional or unpopular ideas for fear of disapproval from peers or superiors. Anonymity allows ideas to surface without fear of repercussion.

In the remainder of this chapter, we will focus predominantly on GSSs as they represent the type of collaboration technology that probably has received most attention from collaboration researchers during the past three decennia. Especially from the late 1980s until the late 1990s, an extensive body of GSS research was published (for overviews, see Dennis et al., 2001; Fjermestad and Hiltz, 1998, 2000;

Nunamaker et al., 1997). Since the mid-2000s, GSS researchers have shifted from a predominant experimental focus to a focus on engineering and design science studies (see, e.g., Kolfschoten and de Vreede, 2009; de Vreede et al., 2009). The extensive scholarly attention for GSS is not surprising as this technology represents one of the few software applications that were originally developed by researchers in universities and subsequently became commercially available. Currently, there are a few dozen commercial GSS applications available in the market. Even though organizations have reported significant benefits from using GSS, sustained use of these applications has been challenging as will be discussed in a later section.

44.3 Types of Team Work: Patterns of Collaboration

Notwithstanding the plethora of collaboration technologies that are available for teams to facilitate their work, fundamentally teams need more than just technology to achieve productive collaboration efforts. Productive collaboration originates from the purposeful alignment of people, processes, information, and leadership with the technology the team uses (de Vreede et al., 2009). A critical component in this socio-technical setting concerns how teams move through their collaborative processes. Researchers have identified distinctly different ways in which a team's problem-solving and decision-making processes proceed, called *patterns of collaboration*. Patterns of collaboration are observable regularities of behavior and outcome that emerge over time when a team moves toward its goals (de Vreede et al., 2006). There are six different patterns of collaboration (Kolfschoten et al., in press; de Vreede et al., 2009):

- *Generate*: To move from having fewer concepts to having more concepts in the set of ideas shared by the group.
- *Reduce*: To move from having many concepts to a focus on fewer ideas deemed worthy of further attention.
- *Clarify*: To move from less to more shared understanding of the concepts in the set of ideas shared by the group.
- *Organize*: To move from less to more understanding of the relationships among concepts in the set of ideas shared by the group.
- *Evaluate*: To move from less to more understanding of the instrumentality of the concepts in the idea set shared by the group toward attaining group and private goals.
- *Build commitment*: To move from fewer to more group members who are willing to commit to a proposal for moving the group toward attaining its goal(s).

Most of the behaviors in which a team engages as it moves through a collaborative process can be characterized by these six patterns. For example, when a team moves through a product development activity, they may *generate* innovation ideas, *clarify* these ideas by re-stating them so that all members understand their meaning, *evaluate* the expected profitability and ease of implementation of each innovation idea, *reduce* the list to the innovations that are most promising, and *build commitment* on the actions to take to develop a complete business case for each innovation.

Researchers have studied phenomena relating to each of the six patterns of collaboration. With respect to the *Generate* pattern, for example, studies report the number of ideas a group produces (Connolly et al., 1990), or their originality, relevance, quality, effectiveness, feasibility, and thoroughness (Dean et al., 2006). People generate by creating new ideas (Reiter-Palmon et al., 1997), by gathering previously unshared ideas (Bock et al., 2005), or by elaborating on existing ideas with additional details (de Vreede et al., 2010). For the *Reduce* pattern, researchers address, for example, the number of ideas in the shared set, the degree to which a reduced idea set includes high-quality ideas and excludes low-quality ideas (Barzilay et al., 1999), and the degree to which reduction of idea sets yields reductions of actual and perceived cognitive load (Simpson and Prusak, 1995). Groups reduce idea sets through idea filtering (Chambless et al., 2005), generalizing ideas (Yeung et al., 1999), or selection (Rietzschel et al., 2006).

Researchers of the *Clarify* pattern focus on, among other things, reductions in ambiguity, reductions in the number of words required to convey meaning, and establishing mutual assumptions (Mulder et al., 2002). Among the phenomena of interest for research on the *Organize* pattern of collaboration are shared understandings of the relationships among concepts (Cannon-Bowers et al., 1993), cognitive load (Grisé and Gallupe, 2000), and the simplicity or complexity of the relationships among concepts (e.g., complex structures may signify sequence, hierarchy, and networks of relationships, which in turn may model, e.g., semantics of chronology, composition, heredity, or causation [Dean et al., 2000]). Research on the *Evaluate* pattern addresses projections of possible consequences of choices and the degree to which those consequences would promote or inhibit goal attainment (Westaby, 2002). Rating, ranking, and inclusion/exclusion are common means of evaluation (Gavish and Gerdes, 1997). Research on such techniques focuses, for example, on the degree to which participants can accurately project the likely outcomes of the proposals they consider (Laukkanen et al., 2002). Finally, phenomena of interest for the *Build Commitment* pattern pertain to the degree to which people are willing to contribute to the group's efforts (Montoya-Weiss et al., 2001). Issues of commitment arise in many phases of group work, starting with the formation of the group (Datta, 2007), and continuing through every proposed course of action and every choice group members make as they move through their activities (Saaty and Shang, 2007). More detailed findings of information systems research in each of these areas are described in the next section.

44.4 Supporting the Patterns of Collaboration

This section examines past research on technology support for each of the patterns of collaboration. For this purpose, the *reduce* and *clarify* patterns will be combined into a pattern called *converge* as research in this area often addresses both patterns simultaneously.

44.4.1 Generate

Idea generation (i.e., brainstorming) is the practice of gathering in a group and generating as many ideas for identifying or solving a problem as possible. Early brainstorming research conducted by Taylor et al. (1958) and later by Diehl and Stroebe (1987) indicated that nominal groups—groups in which ideas are pooled after individuals independently generate them—tended to generate more ideas than groups with team members who collectively interacted to generate ideas. This productivity loss in traditional lab teams occurred due to members being overwhelmed with information (i.e., cognitive load), social loafing, groupthink, and evaluation apprehension (Diehl and Stroebe, 1987). However, these experiments did not focus on teams that utilize strategic collaboration methods and technology. As such, later research showed that, under certain conditions, groups can improve key outcomes using collaboration strategies and technologies (for reviews, see Briggs et al., 1997; Dennis and Valacich, 1999; Fjermestad and Hiltz, 1998).

Nonetheless, effectively communicating pertinent instructions, monitoring participant contributions, dealing with conflict, and facilitating the flow of information/conversation can cause production losses even when a facilitator is charged with managing these issues. Fortunately, when combined appropriately, synergies between collaboration processes and technology can simplify and magnify the power of facilitation techniques. Collaboration technology, such as GSS, helps a facilitator simultaneously display tasks and instructions that group members need to understand in order to minimize the aforementioned challenges of collaboration and maximize the benefits of teamwork. In other words, this technology allows the facilitator to control what decision-making tasks group members see, how they can contribute to the group, and when they can contribute. Thus, it is easier for facilitators to breakdown the collaboration process into simpler, independent activities.

During the idea generation process, technology can also be used to make team members focus on generating ideas rather than evaluating them. When team members assess the merit of ideas or try to

come to consensus while generating ideas, the quality, quantity, and originality of ideas tends to suffer (Basadur and Hausdorf, 1996). Further, technology allows team members to simultaneously contribute a massive number of ideas and transfer those ideas to subsequent collaboration activities, such as moving ideas into categories (i.e., idea organization) or voting on them (i.e., idea evaluation). Technology also can be used to greatly reduce interpersonal conflict that occurs during idea generation. For instance, GSS software can be configured so that participants contribute their ideas anonymously. This anonymity tends to improve collaborative problem-solving outcomes by reducing participants' social fears, such as being judged, retaliated against, or condemned for disagreeing with an authority figure (e.g., supervisor, boss, professor, and client) (McLeod, 2011).

Moreover, being the foundation of most collaborative problem-solving and decision-making efforts, idea generation is typically credited with initiating group creativity and innovation. Creativity is defined as a novel, useful, and socially valued product, idea, or service (Amabile, 1982). Creativity occurs when an ill-defined problem is assessed from multiple perspectives (Mumford and Gustafson, 1988). As such, idea generation is at the core of team creativity because this collaboration pattern requires participants to engage in divergent thinking. Frequently, participants see ideas generated by others that inspire them to make connections and recommendations that they would not have thought of by themselves. Here, ideas from teammates serve as new idea "seeds" that can inspire creativity. To test this assumption, de Vreede et al. (2010) divided large groups into subgroups that were forced to generate ideas in a serial manner by building on the ideas of previously engaged subgroups. This technique proved to be more effective at facilitating creativity than parallel group member idea generation. Other studies have provided further support for the notion that certain types of instructions or methods for generating ideas can be used to maximize group creativity (Sosik et al., 1998; Zurlo and Riva, 2009). These studies highlight the importance of effectively pairing collaboration techniques and technology.

While the aforementioned studies were conducted by means of synchronous collaboration, more and more collaboration is currently being conducted asynchronously online. Asynchronous collaboration overcomes temporal and spatial challenges faced by traditional synchronous collaboration. Although little published research addresses best practices for online asynchronous collaboration, a study by Michinov and Primois (2005) provides great insights. The researchers found that initiating social comparison between participants can improve the productivity and creativity of distributed teams. Specifically, Michinove and Primois learned that motivation to perform can be increased by simply labeling who contributes ideas to group brainstorming sessions. Based on these findings, team leaders and facilitators should consider the trade-offs of idea anonymity when collaboration is asynchronous. It may be the case that the performance-enhancing effects of social comparison may be more valuable to alleviating the "cold" nature of asynchronous collaboration than protecting participants from evaluation apprehension.

Despite the importance of the idea generation stage of collaboration, the best brainstorming interventions provide little utility to a group if generated ideas can cannot be understood, connected, and built upon. Therefore, the following sections describe how subsequent patterns of collaboration improve group problem solving and decision making.

44.4.2 Converge

After generating ideas for identifying or solving a problem, collaborators must *converge* on the shared knowledge necessary to address the problem. Convergence is a critical activity in group work that lays the foundation for shared understanding and the overall advancement of a group's task. To converge has been defined as "to move from having many concepts to a focus on and understanding of a few deemed worthy of further attention" (de Vreede and Briggs, 2005). Group work concerns convergence when a group deliberates on and reduces the amount of information they have to work with (de Vreede and Briggs, 2005).

Essentially, convergence lays the foundation for shared understanding and the overall advancement of the group's task (Davis et al., 2007). In doing so, a primary goal of convergence is to reduce a group's cognitive load in order to address all concepts, conserve resources, have less to think about, and achieve shared meaning of the concepts. However, convergence is time consuming and has been shown to be a painful process for groups (Chen et al., 1994; Easton et al., 1990). de Vreede and Briggs (2005) identify four aspects or subprocesses that can be combined in order to create useful variations in convergence activities. These include (1) judging or identifying which of the existing concepts merits further attention; (2) filtering or selecting a subset from a pool of concepts that will receive further attention; (3) generalizing or reducing the number of concepts under consideration through generalization, abstraction, or synthesis and then eliminating the lower-level concepts in favor of the more general concept; and (4) creating shared meaning or agreeing on connotation and establishing a shared meaning or understating about the labels used to communicate various concepts.

To date, convergence has received limited scholarly attention. Researchers have argued that convergence activities in group work are complicated due to a variety of reasons, including information overload at the start of a convergent task, the cognitive effort that is required for convergent tasks, and the need for a higher granularity of meeting ideas to be stored (i.e., meeting memory) for future decision making and analysis (Chen et al., 1994). To address these issues, GSS researchers have argued about the most effective mode and means of communication for convergence issues. For example, Dennis and Valacich (1999) propose that verbal communication is most appropriate when a team needs to converge and establish shared meaning. Verbal communication is mostly recommended for efficiency, because it provides the fastest feedback. Other researchers argue for combining electronic and verbal communication modes during convergence: participants can benefit electronic tools during convergence due to the fact that key concepts can be identified and represented with a minimum of cognitive load on the group members (Briggs and de Vreede, 1997). These insights have been consolidated in media synchronicity theory (MST) that suggests that individuals would prefer highly synchronized communication media (i.e., face-to-face) for convergence communication, which relate to shared understanding, and less synchronized media (e.g., e-mail) for conveyance communication, which relates to facts or alternatives (DeLuca and Valacich, 2006; Dennis et al., 2008). Furthermore, MST argues that decision-making tasks require convergence before proceeding to the next task as well as the conveyance of specific information (e.g., facts or alternatives) (Dennis et al., 2001).

In contrast to the research that addresses convergence issues from the group members' perspective, recent research from a facilitator's perspective has shown that facilitators find convergence to be one of the least demanding patterns of collaboration, behind divergence (Hengst and Adkins, 2007). Yet, the same study found building consensus to be the most demanding pattern of collaboration, and the authors suggest that building consensus is most often done with convergence and organization subprocesses. Other researchers have proposed a set of performance criteria to provide a framework to compare and contrast different convergence techniques (Davis et al., 2007). These criteria include both result-oriented (e.g., level of shared understanding and level of reduction) and process- or experience-oriented criteria (e.g., ease of use for the team members and satisfaction with technique by the facilitator). Initial studies have applied some of these criteria (see, e.g., Badura et al., 2010), but clearly more research is required in this area.

In conclusion, a review of previous research suggests there is little structural attention on the topic of convergence. Moreover, there is very limited, detailed guidance available how to best structure convergence activities in groups (Briggs et al., 1997; Hengst and Adkins, 2007).

44.4.3 Organize

Groups cannot solve problems and innovate by means of simply compiling ideas and developing a shared understanding of them. As a result of idea generation and convergence, a large amount and complexity of the information shared between collaborators puts a burden on their time and attention.

In order to reduce demands on limited human resources and to overcome limitations on understanding, groups need to *organize* the information they generate. This section examines what is known about the organization stage of the collaborative problem-solving process and how this phenomenon has been conceptualized.

At the core of the organization stage of the decision-making process is the idea that collaborative organization activities are intended to facilitate greater understanding of the relationships among concepts. Little research has taken place in the general area of organizing information as team work. However, a special form of the organize pattern, *group modeling*, has received some focused attention (Renger et al., 2008). Broadly speaking, through collaborative modeling participants are able to create a shared understanding about a collection of concepts and their interrelationships. Often group model activities take place as part of an effort to represent a system design.

Early studies on IT-supported versus "pencil and paper" design modeling established that facilitation practices and IT can be leveraged to greatly improve collaborative design modeling processes and outcomes (Dean et al., 1995). For instance, the use of IDEF0 modeling was initially limited to collaboration in small groups because a group would first use flip charts, whiteboards, or transparencies to delineate information they were attempting to organize, then a facilitator would have to transcribe that information into a single-user tool that created graphical models. This process frequently led to misinterpretations of data and/or group members feeling that they had less control over the models than desired (Renger et al., 2008). Later group modeling systems integrated GSS and IDEF0-specific functionalities and allowed for active participation such that several participants would have direct control over how concepts are graphically, syntactically, and semantically modeled (Dean et al., 2000; Dennis et al., 1999). Other group modeling approaches that have been successfully employed in field settings include jointly understanding, reflecting, and negotiating strategy (JOURNEY Making) (Ackermann and Eden, 2005), which uses cognitive mapping techniques to support strategic planning and policy making, and group model building (Andersen et al., 2007), which refers to "a bundle of techniques used to construct system dynamics models working directly with client groups on key strategic decisions" (Andersen et al., 2007, p. 1).

The study of collaborative modeling has evolved with its use in practice, yet quantitative studies on specific comparative strengths and weaknesses of various technology-supported modeling methods are scant. A meta-analysis conducted by Renger et al. (2008) examined various outcomes in the collaborative modeling literature. It was found that across 22 group modeling studies, six studies yielded positive effectiveness results, three studies found high levels of participant satisfaction, and five studies discovered evidence of shared understanding resulting from certain collaborative design approaches. Thus, collaborative modeling has yielded effective outcomes when used to facilitate the organization stage of collaboration. Additional research is needed to identify context effects on collaborative modeling, as well as head-to-head comparisons of different modeling methods to determine which approaches are most effective under specific circumstances.

44.4.4 Evaluate

Another critical part of team work occurs when groups *evaluate* the merit of ideas. Admittedly, evaluation tends to happen at each stage of a collaboration process, but the most effective team efforts tend to prevent premature idea evaluation. That is, the generation, expansion, and linking of ideas tends to be disrupted when ideas are evaluated during or before convergence or organizing activities. However, once a group has converged on a set of ideas, this new found shared understanding must be leveraged to identify optimal options.

Two primary methods are used to evaluate the merit of ideas. First, ideas can be compared head-to-head using a rank-order or single criterion voting system. Second, a multi-criteria decision-making system can be utilized to develop a better understanding of the strengths and weaknesses of each idea. Dean et al. (2006) provide a thorough review of various criteria used to

evaluate problem solutions in research studies conducted from 1990 to 2005. This study supports findings from MacCrimmon and Wagner (1994) that suggest that most decision-making criteria used in previous research tend to fall under one of four categories: novelty, workability, relevance, and specificity. Further, Dean et al. emphasized that when assessing the creativity of ideas, the constructs *originality* and *quality* succinctly embody the essential characteristics of creativity, as defined by Amabile (1996). Interestingly, Dean et al. conveyed that more accurate assessments of ideas occur when multi-criteria evaluations are kept separate, rather than combined into a summated or multiplicative unidimensional rating.

In all, ideas are relatively easy to compare head-to-head, but multi-criteria evaluations provide richer data. Further, many criteria have been utilized in previous research to effectively assess collaboratively generated and distilled ideas, but criteria need not be limited to these recommendations. Depending on the purpose or goal of collaborative decision making, criteria should be adjusted to assess customized considerations such as ease of implementation, cost, and anticipated impact.

44.4.5 Build Commitment

The fifth and final pattern of collaboration is building commitment. In the research literature, the terms building commitment and building consensus are often used interchangeably. Building commitment or consensus typically wraps up group decision-making efforts. For collaborative efforts to succeed, groups must find solutions that balance the differing requirements or needs of stakeholders, while acknowledging that it may not be possible to satisfy all needs of all stakeholders (Simon, 1996). Otherwise, individual stakeholders whose interests are thwarted by group processes may themselves be in a position to thwart the group's success. Thus, building consensus is a critical aspect of collaborative efforts.

To support decision making by teams and groups in consensus building, both rational (see, e.g., Yu and Lai, 2011) and social preferences (see e.g., Dong et al., 2010) should be considered. While some GSS have been developed to calculate optimal solutions with inclusion of both rational and social perspectives, these calculations are often complex and therefore less transparent. Thus, there is a possibility that the users may not trust them to represent team consensus. Even more importantly, GSSs aid in decision making, but to build consensus, groups also need to debate varying perspectives and overcome differences to arrive at a mutually agreeable decision (Er, 1988). Accordingly, one of the foci of GSS research has been to create the optimal conditions to achieve consensus. For example, Chen et al. (2012) suggested an adaptive consensus support model for group decision-making systems. Using this model, GSS can evaluate the comments of the contributors and provide suggestions for modification in order to enable progression toward consensus. Moreover, the system is also interactive so that the contributors can further modify these suggestions allowing the GSS to create an increasingly accurate model of consensus.

In addition to improving consensus building models, GSS research has also been extended to accommodate distributed decision making through the use of analytical algorithms to facilitate consensus. For example, Tavana and Kennedy (2006) used a strategic assessment model of consensus to enable distributed teams identify strengths, weaknesses, opportunities, and threats of the Cuban missile crisis situation. This model enabled consensus using various intuitive processes including subjective probabilities, an analytical hierarchy process, and environmental scanning to achieve consensus through focused interaction and negotiations among an international group of participants. However, it has been argued that these and other decision conferencing systems need to consider the cultural differences among international participants and adjust for it in order to achieve greater success (Quaddus and Tung, 2002).

Groups that use GSS tend to outperform their face-to-face counterparts on the aspects of information exchange and quality. In their study, Lam and Schaubroeck (2000) compared groups that were using GSS to groups that were involved in face-to-face decision making. They found that, in the absence of a pre-discussion consensus, the GSS groups were significantly more efficient in reaching a

consensus about the superior hidden profile candidate than the face-to-face groups. In addition, being in a GSS facilitated group tended to shift the individual preferences toward group consensus more strongly.

The use of GSS may not only make the process of decision making more efficient, but it also offers an opportunity for researchers to evaluate the data in order to analyze patterns and recommend improvements to the process on a post hoc basis. On a simple level, initial levels of consensus can be statistically evaluated following a voting process by which participants use Likert-type scales (e.g., 1 = *strongly disagree* to 5 = *strongly agree*) to assess the merit of ideas (e.g., quality, novelty, and ease of implementation). Specifically, the average rating and standard deviation of each item are calculated. Then, the team typically agrees on ideas with the highest ratings and lowest standard deviations as their preferences. Moreover, a large standard deviation suggests participants do not agree on the merit of an idea. Such ideas should be further discussed, and then voted on again, to ensure the lack of consensus is due to a true disagreement, rather than a misunderstanding of the idea.

Other, more complex, methods and algorithms can also be used to assess group consensus. For example, a study by Ngwenyama et al. (1996) showed that the data that are collected by the means of GSS allow facilitators to identify the issues that have been most contentious as well as the individual and collective positions on all the issues raised. In addition, these data can also be useful to facilitators to analyze the group preferences and the available alternatives that support consensus formation. Similarly, in another study, a GSS-based consensus building approach was utilized to analyze a group's creative problem-solving and decision-making processes (Kato and Kunifuji, 1997). Using the GSS enabled the researchers to combine creative thinking methods with a consensus making process to solve complicated problems. The participants who used the combination of the two methods could construct the appropriate evaluation structure interactively and choose the optimal alternative in a rational manner.

Finally, the application of GSS has also moved beyond the laboratory and corporate decision making into the area of political disputes among conflicting parties. One such example can be found in the conflict resolution and consensus building effort that was successfully conducted by the water authorities in northwest Iran (Zarghami et al., 2008). In this context, a GSS was used to identify the criteria and rank the water resource projects in the area. This system guided the supervisor who was in charge of the group decision-making problem and allowed him to negotiate with the stakeholders effectively in order to resolve conflict and achieve consensus.

These studies are but a few that illustrate the significance of GSS in consensus building. The contribution of GSS to consensus building is far from saturated. With the advent of new technologies and the changing nature of groups and teams, GSSs have an opportunity to evolve and assimilate new ways of processing information and reaching consensus. For example, keeping up with the changing nature of technology, GSSs are evolving to a new level and may incorporate virtual reality and virtual interactive modeling (VIM) to assist with consensual decision making in groups (Jam et al., 2006). In their study, Jam et al. (2006) conducted a controlled experiment to evaluate the effectiveness of VIM in distributed groups. The results showed that the use of VIM leads to greater efficiency of decision making, greater satisfaction with the process, and improved group member attitude. Such visualization technologies can potentially help distributed groups integrate information easier and improve their communication.

44.5 Organizational Effects of Technology-Supported Collaboration

As the previous section shows, GSSs have been utilized in different ways and have yielded various outcomes in organizations. Early studies in university environments (e.g., Gallupe et al., 1988) were followed by studies at organizational sites (e.g., Grohowski et al., 1990). GSSs have since been commercialized and are present in an increasing number of domestic and international contexts (Briggs et al., 2003).

Interestingly, collaboration technologies such as GSS do not always render the effects that were anticipated. As suggested by adaptive structuration theorists, organizations may utilize technologies in ways that were originally not intended (DeSanctis and Poole, 1994).

Yet, field research on GSS predominantly paints a positive picture (for an overview, see Fjermestad and Hiltz, 2000). Among field studies with GSS there are comparatively few that focus on organizational groups that used GSS in their own environment, that is, the organization of which they are part. Most studies on real groups report on visits that the group made to facilities outside their organization, most often on the premise of the researchers involved. It is important (and convenient) to do such studies in university contexts where variables can be more systematically explored and sufficient sample sizes be developed under more controlled circumstances. Exceptions to this practice include the use of software aided meeting management (SAMM) by the internal revenue service (IRS) in New York City (DeSanctis et al., 1992) and GroupSystems at the U.S. Navy ThirdFleet (Briggs et al., 1998).

Another limitation of GSS field studies is that most have been executed in North American settings, making it difficult to draw generalizations. Exceptions are reported in overviews in Nunamaker et al. (1997) and de Vreede et al. (1998). An interesting cross-cultural comparison of in situ GSS experiences was reported by de Vreede et al. (2003). Their work compared the experiences from four case studies, two in the United States and two in the Netherlands. Each case study used a GSS called GroupSystems:

1. *International Business Machines*: GroupSystems was introduced at IBM in 1987. A series of studies at this site followed that demonstrated that GSS technology could be effectively introduced in organizational environments (Grohowski et al., 1990; Vogel et al., 1990). Based on success at the first facility, IBM installed the technology at six more sites over the following year and similarly expanded their internal facilitation support capabilities (Grohowski et al., 1990; Martz et al., 1992; Vogel et al., 1990). IBM continued expanding internally to 24 sites and beyond with the same format of use, that is, preplanned session agendas with facilitation support throughout the meeting process. The facilitation role was institutionalized with several generations of facilitators emerging from a wide variety of backgrounds and levels of experience with group and organizational dynamics.
2. *Boeing Aircraft Corporation*: Encouraged by reports of IBM's success, Boeing Aircraft Corporation decided in 1990 to conduct a carefully controlled pilot test of GroupSystems in their organization. Boeing collected data so that a business case could be developed either in favor of or against the widespread use of GSS to support their projects. After 64 sessions, costs were evaluated. The project time, or number of calendar days required to produce the deliverables, was reduced by an average of 91%. The man-hour cost savings averaged 71%, or an average of $7,242 per session, for a total savings of $463,488 over the 64 sessions (Post, 1993). This was despite the fact that expense figures included the initial start-up of installing the meeting room technology, training facilitators, and collecting the measurement data.
3. *Nationale-Nederlanden (NN)*: Part of the ING Group, NN is the largest insurance firm in the Netherlands and one of the market leaders in Europe. NN was introduced to GroupSystems at Delft University of Technology in 1995. Based on early success, NN continued to use GSS and develop its own internal facilitation capabilities (de Vreede, 2001). Following the successful use at NN, other parts of the ING Group also adopted to use the technology.
4. *European Aeronautic Defense and Space Company, Military division (EADS-M):* EADS-M is a cooperation of four European companies in producing the Eurofighter and other military aircrafts. EADS-M was first introduced to GSS by Delft University of Technology in 2001. Based on a successful pilot study on GSS, the company acquired a GroupSystems license and had a number of internal facilitators trained.

The cross-case findings from these four organizations are presented in Table 44.2 (all aspects, except savings, on a 5-point Likert scale, 5 being most positive). Overall, the results show that the application of GSS in each of the organizations can be considered successful, both in terms of the actual results that were

TABLE 44.2 Cross-Case Findings on Organizational Use of GSS

Aspect	IBM	Boeing	NN	EADS-M
Efficiency				
Session is efficient	3.9	4.0	4.0	4.3
Person-hours savings	55.5%	71.0%	53.0%	49.7%
Calendar time savings	92%/89%[a]	91.0%	57.7%	33.3%
Effectiveness				
GSS more effective than manual	4.2	—	4.0	4.1
GSS helps to achieve goals	4.1	4.0	3.9	4.0
Initiator's evaluation of outcome quality	4.4	4.1	3.9	4.3
User satisfaction				
Satisfaction with GSS process	4.1	—	4.1	4.3
Willingness to use GSS in similar projects/activities	4.2[b]	4.4	4.2	4.5

[a] Based on 11 and 59 sessions, respectively.

[b] For brainstorming activities.

achieved (e.g., time savings) and in terms of the participants' perceptions (e.g., meeting satisfaction). In each of the organizations, the expected savings would significantly outweigh the expenses for running the technology and hiring (technology) support staff (e.g., facilitators). These findings were particularly interesting given that the individual cases were conducted over a time span of 16 years in four very different organizations in terms of business focus and national/corporate culture.

What is even more interesting than the positive findings in the individual case studies is that although the results in each situation led to management decisions to implement the technology in the organization, the use of the GSS facilities slowed down over time and in three of the four cases the facilities were disbanded. This illustrates that the technology by itself may appear to represent a positive business proposition, but its actual sustained use over time is influenced by other factors. A stream of research in the area of Collaboration Engineering identified that the root cause behind the abandonment of seemingly successful GSS facilities concerned the need to use professional facilitators to let teams get value out of the technology. That is, the technology itself is too complex to configure and align with the team process for groups to do by themselves. Facilitators can be a costly option for an organization. Thus, many groups that could benefit from their services do not have access to them. Further, it turned out that it can be challenging for an organization to retain its facilitators because they are often either promoted to new positions or they leave the organization to establish consulting practices (see, e.g., Agres et al., 2005). Since then, researchers have pursued ways to reduce the reliance on professional facilitators to benefit from GSS-enabled collaboration. One particularly promising avenue has been to codify facilitator expertise in a collaboration design pattern language called ThinkLets (de Vreede et al., 2006, 2009). ThinkLets are like a Lego™ toolkit that allows collaboration engineers click together processes that can be easily transferred to domain experts in organizations to execute by themselves. A number of successful thinkLet-based interventions are described in de Vreede et al. (2009).

44.6 Future Directions for Research on Technology-Supported Collaboration

This final section presents three important directions for future research on technology-supported collaboration. The overview that has been presented in this chapter shows that, under the right circumstances, teams can dramatically benefit from the use of collaboration technology to support their problem-solving and decision-making activities. To unlock this potential, the key challenge for teams is twofold: First, they must purposefully align the people, process, information, and leadership specifics

of a collaborative effort with the capabilities that the technology provides. Second, to keep reaping the benefits from the technology, they must find ways to create self-sustaining routines that they can use repeatedly to execute a technology-supported collaborative work practice.

The first of the future directions described addresses this challenge. The other two future directions illustrate that this challenge is even more important to address as team collaboration is moving into new technological environments that bring about a renewed focus on designing and sustaining productive technology-supported team efforts.

44.6.1 Task-Specific Collaboration Applications with Build-In Facilitation Guidance

To reduce the need to rely on professional facilitators to guide team efforts, researchers have begun to explore and prototype ways to build facilitation expertise into collaboration technology. The guiding research question is, *How can collaboration expertise be packaged with collaboration technology in a form that nonexperts can reuse with no training on either the collaboration tools or techniques?* To answer this question, researchers are developing a new class of software called Computer Assisted Collaboration Engineering system (CACE). CACE supports the design, development, and deployment of technology-supported collaborative work practices. An example of a CACE is the ActionCenters system (Briggs et al., 2010; Buttler et al., 2011; Mametjanov et al., 2011). ActionCenters supports the rapid design, configuration, and deployment of software applications custom tailored to support specific collaborative work practices. Each application presents the users with a series of activities for achieving their task. Each activity provides the users with just the tools, data, communication channels, and guidance they require for that activity, and nothing else. The applications can therefore appear very simple and obvious to the users, while providing powerful capabilities. The core of the ActionCenters environment is a collection of loosely coupled, highly configurable collaborative components like shared lists and outlines, shared graphics, polling tools, audio and video channels, and shared document repositories. In the ActionCenters CACE environment, the collaboration engineer snaps these elementary components together and configures them to behave as if they were a tightly integrated, task-specific system without having to write a new code. A CACE is fundamentally different from a GSS in that the GSS provides a generic, configurable toolkit for a plethora of collaboration processes whereas the system built in a CACE is a task-specific application that has all required configurations predefined and guides the users through each step in their process.

A CACE system can be seen as a design studio for creating technology support for repeatable group processes without writing any new code (see Figure 44.1). With a CACE system, collaboration engineers can embed different types of collaboration expertise into the collaborative tools in a format that enables practitioners to execute the technology-supported work practice with no training on either the tools or the collaboration techniques. The resulting collaborative application provides end users with a sequence of screens that represent the activities that together make up the team task. Each screen provides users only with the functionality that they require for that activity in the sequence. For example, Figure 44.2 depicts a screen at runtime in a requirements negotiation process. The banner heading at the top is implemented with an HTML control. The numbered list in the middle with its input panel is a configured outliner component. The caption-balloon icons to the right of each outline heading are links to a subordinate outliner component. When a caption balloon is clicked, the subordinate outline component pops up configured to appear and behave as a comment window, so users can comment on any heading in the main outline.

Pilot studies with ActionCenters for five technology-supported collaborative work practices have demonstrated that collaboration engineers could create complete, task-specific collaboration systems in hours or days that would have required several person-years of effort using conventional approaches. In a pilot study of a domain-specific creative problem-solving application, eight groups

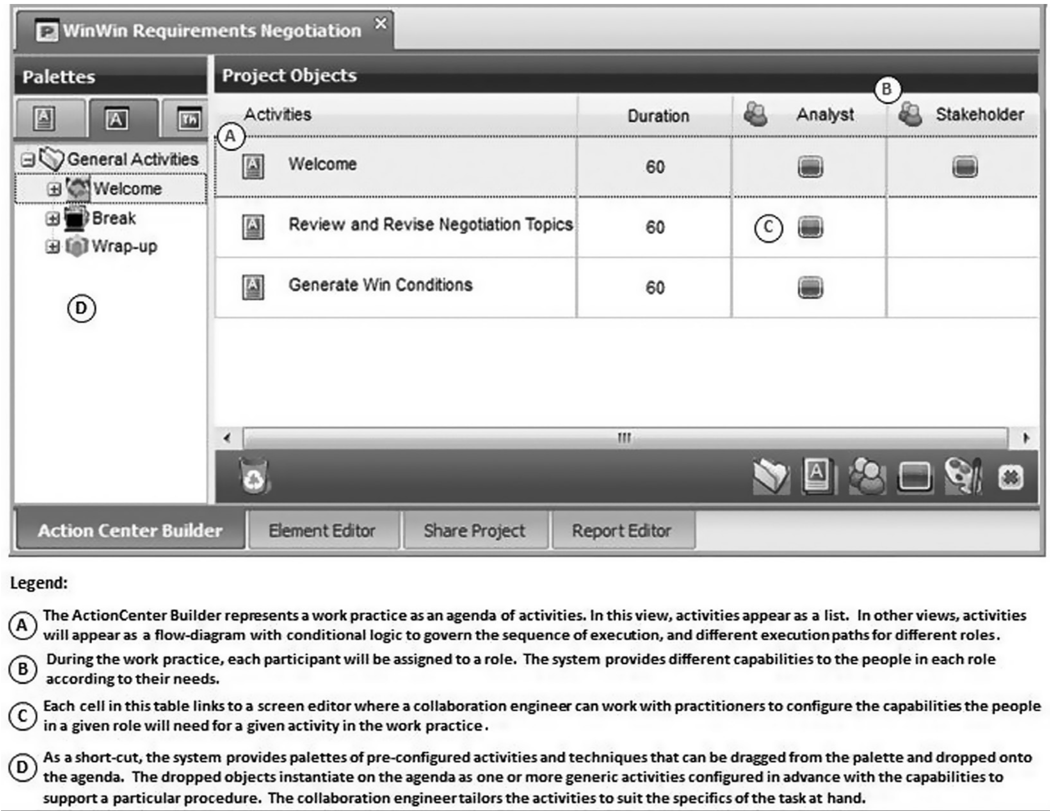

FIGURE 44.1 Screenshot of the ActionCenters CACE studio.

FIGURE 44.2 Run-time appearance of a screen in a requirements negotiation process step.

of practitioners with no prior experience on collaboration technology and no knowledge of the collaboration techniques embedded in the work practice nonetheless executed successfully a sequence of five techniques under the guidance of the ActionCenters application. Each group achieved its goals. Current efforts are under way to test the ActionCenters more rigorously in a program of laboratory experiments, which will be followed by a series of field trials.

44.6.2 Virtual Worlds

In the recent years, much excitement has built up around a new concept of work spaces called metaverses or virtual three-dimensional (3-D) spaces. Metaverses are usually used for sharing information, creating personal virtual images (avatars), and manipulating virtual objects. They are immersive virtual worlds (VWs) where avatars interact with each other and with software agents, using the metaphor of the real world but without its physical limitations (Davis et al., 2009). VWs allow teams to move beyond simple electronic conversation and document distribution by providing an environment where people can also share a communal space with others.

Extrapolating from Media Richness Theory (Daft and Lengel, 1986) and Media Synchronicity Theory (Dennis et al., 2008), researchers suggest that users of VWs may be more engaged during VW collaboration than low-tech distributed collaboration because VW users experience co-presence—a feeling of shared social and physical space that adds an element of interpersonal realism to collaborative interactions. Further, the accessibility and multiple means of communication inherent to VWs makes it a powerful platform for supporting collaboration. Specifically, in VWs, users have many communication tools to their disposal, such as text-based messaging, video conferencing, object creation/sharing, audio, and even GSS. Research to date has shown that collaboration in VWs can be a motivating, engaging, productive, and satisfying experience for team members. Yet, teams face various challenges at the same time, including but not limited to the need to master the skills to smoothly operate their avatars, the risk of social loafing from team members, and the difficulty for team leaders to monitor participants' emotional states and establish rapport. For an overview of VW collaboration research to date, see Boughzala et al. (2012).

VWs are currently facing some major challenges to become a broadly accepted environment for team collaboration. In fact, VWs appear to be losing some popularity, especially as society is moving toward mobile technology that does not yet suitably supports VWs, such as cell phones and tablets. Also, researchers found that despite richer communication tools, the absence of face-to-face interaction makes convergence and consensus processes difficult as the body language, perceptions, and feelings of participants are difficult to assess in VWs (Wigert et al., 2012). Notably, much of the challenge of using VWs can be attributed to the difficulty faced when trying to effectively manipulate avatars to display appropriate body language. As such, future research is needed to determine how VW collaboration can be further enriched through advances that focus both on the technology itself and the processes that teams execute.

44.6.3 Crowdsourcing

The third and final direction for future research relates to collaboration through social media. Social media have expanded the capability of collaborative problem solving into social levels including online crowds of employees, professionals, amateurs, producers, and consumers. This has given rise to a new phenomenon, which is commonly known as *crowdsourcing* (Howe, 2008) that can be defined as a collaboration model enabled by social web technologies to solve organizational problems in partnership with online communities (Oh et al., 2012). Other popular terms include "mass collaboration" (Tapscott and Williams, 2006), "open collaboration," "collective intelligence" (Surowiecki, 2005), and "co-creation" (Kazman and Chen, 2009). All these terms put online users in the center of collaboration processes, while they have not been considered as important actors in traditional collaboration models.

In crowdsourcing, there are two modes of collaboration (closed collaboration versus open collaboration), which have distinctively different collaboration processes. Table 44.1 illustrates that "closed collaboration" focuses on *finding* the best solution out of many submitted ones, whereas "open collaboration" focuses on *facilitating collaboration* among undefined large number of online community members to solve problems (Table 44.3).

TABLE 44.3 Different Modes of Collaboration in Crowdsourcing

	Closed Collaboration	Open Collaboration
Types of problem	• Structured problem • *Organizations define a problem* and broadcast the defined problem to an online community so that community members can submit solutions to the organization Exemplary Problem: "A one-part adhesive is required that is activated at room temperature. The adhesive should have a minimum set-strength upon activation for gluing a fixed substrate on metals and synthetics (polymers) which can then be fully cured by other methods … Theoretical proposals (no verified method data) will be considered for a lesser reward." (*taken from InnoCentive.com*)	• Unstructured problem • Organizations broadcast an unstructured question to an online community so that the community can (1) identify and define specific problems in parallel ("brainstorming") and (2) clarify and evaluate each problem by commenting or voting to reduce the large number of suggested problems into a selection of the best few ideas worthy of more focused attention ("convergence") Exemplary Problem: "We've received many suggestions about closing select streets temporarily to create more opportunities for bicycling, walking, and events such as farmers markets and art walks. How often should we close streets for these types of activities?"(*taken from ideas.LA2B.org*)
Way of finding solution	The organization *selects* the best solution from a large number of solutions submitted by the online community. Collaboration between online community members is not allowed. Therefore, collaboration features such as voting, commenting, rating, and sharing in the web interface design are not important	The organization *facilitates collaboration* between online community members. The organization determines the best solution considering the results of both brainstorming and convergence activities. Therefore, collaboration features such as voting, commenting, rating, and sharing in the web interface design are important
Examples	*mTurk.com.com, InnoCentive.com, YourEncore.com, oDesk.com, freeLancer.com*	*Threadless.com, CambrianHouse.com MindMixer.com, CrowdCast.com, BrainReactions.net*

Crowdsourcing is based on two underlying assumptions: (1) a larger number of people can solve difficult or complex problems better than a small number of people and (2) a team or group that has high collective intelligence is more likely to excel in complex problem solving. Compared to traditional settings such as GSS, a distinctive feature of social media–driven collaboration is that it highlights the potential that a large online *amateur crowd* can be smarter than a handful of *organizational professional experts* in problem solving. To this end, Surowieck (2005, p.10) suggests four conditions that need to be met for online crowds to make wise decisions to solve problems collectively: (1) creating sufficient diversity of opinion, by which each individual involved has some private information, even if it is just an eccentric opinion; (2) maintaining independence, wherein each person's opinion or decision is not influenced by those around them; (3) enabling decentralization, through which individuals can specialize and tap into local sources of knowledge; and (4) facilitating aggregation, which stresses the importance of mechanisms for translating many private opinions or decisions into a collective decision. These notions are not entirely new. Apart from the fourth condition ("aggregation"), the first three conditions have been repeated research questions in collaboration science research in general and GSS research in particular. Although it is still an under-researched area, recent studies have begun to pursue the notion of "convergence," which is comparable to Surowiecki's notion of "aggregation." Finding ways to effectively create and sustain the conditions that Surowieck outlines provides an exciting opportunity for collaboration technology researchers in general and GSS researchers in particular.

44.7 Summary

The advent of ubiquitous computing power and access to the Internet has enabled team collaboration across boundaries of time, place, institutions, and culture. Modern collaboration processes have become increasingly reliant on advanced collaboration technologies and systems. Notwithstanding the clear value that these technologies bring, their use in organizations and teams is not without challenges. Collaboration researchers and practitioners have developed and leveraged new collaboration techniques and applications to address many challenges inherent to IT-supported collaboration. The aim of this chapter was to provide an overview of how IT in general and collaboration technologies in particular support team problem solving and decision making to improve their performance.

First, a classification scheme was presented to organize the different types of collaboration technologies teams can use in various situations. Next, some underlying principles of IT-supported collaboration were introduced in the form of six patterns of collaboration: *idea generation*, *reduction*, *clarification*, *organization*, *evaluation,* and *building commitment*. An overview was provided to show how past research has offered insights on supporting groups in each of these patterns through collaboration technology, with a special focus on GSS. Next, an account was given on the organizational value that organizations can derive in terms of cost savings and productivity gains through the use of GSS-supported team processes. Finally, three important directions for future research and practice were introduced: (1) the development of a new generation of collaboration technology in the form of CACE environments that enable collaboration engineers to snap together task-specific collaborative applications with embedded facilitation guidance without having to write software code, (2) the use of virtual worlds as an environment to provide a rich online collaboration experience through the use of avatar representations of team members, and (3) the emergence of crowdsourcing as a force for superior collaborative problem solving through the active involvement of large numbers of participants. Together these directions represent both an opportunity and challenge for researchers to transfer and expand insights from past research on technology-supported group work to future research efforts.

Glossary

Audio conferencing tools provide a continuous channel for multiple users to send and receive sound while video conferencing tools allow users to send and receive sound or moving images.

Convergence is the action of moving from having many concepts to a focus on and understanding of a few concepts deemed worthy of further attention.

Conversation tools are primarily optimized to support dialog among group members. E-mail is a widely used conversation tool as well as short message service (SMS) (i.e., cell phone text messaging), which is becoming increasingly common.

Crowdsourcing is used in order for the job of a specific agent or team to be outsourced to a larger, undefined group in an open call for solutions.

Desktop sharing tools allow the events displayed on one computer to be seen on the screens of other computers.

Enterprise analysis is a collaborative design model building approach that concentrates on collaboratively built models as a goal in itself rather than as a transitional object.

Group dynamics tools are optimized for creating, sustaining, or changing patterns of collaboration among individuals making a joint effort toward a goal.

Group model building refers to a bundle of techniques used to construct system dynamics models working directly with client groups on key strategic decisions.

Group support systems integrate collections of group dynamics tools to move groups seamlessly through a series of activities toward a goal, for example, by generating ideas in one tool, organize them in another, and evaluating them in yet another (e.g., GroupSystems or MeetingWorks).

Idea generation (i.e., brainstorming) is the practice of gathering in a group and generating as many ideas for identifying or solving a problem as possible.

Polling tools are a special class of jointly authored pages, optimized for gathering, aggregating, and understanding judgments, or opinions from multiple people.

Problem structuring methods (PSM) refer to a broad variety of methods and tools that have been developed mainly in the United Kingdom to cope with complexity, uncertainty, and conflict.

Search engines use search criteria provided by users to retrieve digital objects from among vast stores of such objects (e.g., the World Wide Web, the blogosphere, and digital libraries).

Shared editor tools are typically a jointly authored page optimized for the creation of a certain kind of deliverable by multiple authors.

Shared file repositories provide mechanisms for group members to store digital files where others in the group can access them.

Social tagging allows users to affix keyword tags to digital objects in a shared repository.

Syndication tools allow a user to receive a notification when new contributions to pages or repositories they deem to be of interest (e.g., blogs, wikis, and social networks).

Virtual worlds (VWs) are online virtual environments in which users interact using 3-D avatars in a shared space.

Organizational Adoption of New Communication Technologies

Jonathan Grudin
Microsoft Research

45.1 Introduction

45.1.1 Why Today's Digital Technologies Are Different

Telegraph, telephone, photocopying, fax, courier mail, digital PBXs—organizations have steadily appropriated new communication technologies. In the digital era, e-mail came first. It had far fewer features than today, it was expensive, and adoption came slowly. Organizations had time to gauge the likely costs and benefits and to prepare.

This has changed. A wave of popular new communication technologies followed e-mail. Instant and text messaging, wikis, blogs and microblogs, social networking sites, video—many with free versions that employees can download, access via browsers, or bring in on smart phones. Many are used first for personal tasks. Work–life boundaries are blurring. The changed dynamic has benefits for an organization—acquisition and training costs are lower than they once were. It also creates challenges: Employees' preferences and behaviors can conflict with a planned deployment or produce a de facto deployment that takes management by surprise.

Historically, new technologies often find industrial uses prior to widespread domestic use—clocks, sewing machines, and telephones were initially too expensive for most consumers. Early computers were expensive, but because governments placed them in universities starting in the 1950s, many students entered industry experienced with e-mail, text editing, and other computer use. Abetted by

Moore's law and rapidly declining prices, students and other consumers continue to embrace many digital technologies before enterprises give them careful consideration.

This chapter focuses not on architecture and only a little on design; my concern is organizational use of messaging, wikis, weblogs, and social networking sites—communication technologies that support information sharing and coordination as well.

After a discussion of relevant terminology, I will briefly describe still-relevant high-level lessons from an earlier era. These inform two frameworks that I find invaluable in understanding seemingly contradictory outcomes that accompany widely used communication and collaboration systems. To motivate these frameworks, the first widely embraced digital communication technology, e-mail, is considered. The focus of this chapter then moves to studies of enterprise experiences with these new technologies that some employees first use spontaneously. The discussion and conclusion cover key points and forward-looking considerations based on the observations and analyses.

45.1.2 Terminology for Organizational Process

Information systems (IS) and computer science (CS) use the same terms to mean different things. IS generally has a longer-term perspective, from the first glimmer that something might be built or acquired to the system's retirement years or decades later. CS, even within software engineering, has a more limited and more technical focus.

The terminology of IS reflects the perspective of a manager or IT professional. Adapting the framework of Munkvold (2002), *initiation* is the identification of needs and possible solutions, *adoption* is the organizational sign-off on a plan, *adaptation* is the development or acquisition and installation of the technology, training plans, and polices governing use, and *acceptance* signals actual use by employees, which is followed by *operation and maintenance*. The entire process is called the organizational *implementation*. A CS perspective is that of a developer or user, with the sequence *requirements analysis*, *development* (also called *implementation*) or *acquisition*, and *adoption*, the latter representing actual use.

Why is a dry discussion of terms of interest? Partly because misunderstanding terms impede communication and exploration of the literatures. But a deeper difference is seen in the contrast between *acceptance* and *adoption* to identify system use. Historically, users of organizational systems had no discretion: Their task was to *accept* a system. CS focuses on professionals and consumers who have discretion—they can *adopt* a product or ignore it.

As suggested by this emphasis on the distinction between passive acceptance and active adoption, this chapter focuses on users' behaviors more than technical characteristics of technology. In organizations today, unlike the past, employee use of some technologies is initially discretionary. This aligns with the CS perspective, adoption, and can represent a change and challenge to IS managers and IT professionals.

Recapping, in the traditional systems perspective of IT professionals, once a technology is rolled out and found to work technically, a key process is complete, whether or not the technology is used at all. From a user perspective, the crucial adoption process *begins* at this point and focuses on whether the targeted individuals or groups *use* the technology. If included, a training perspective is in between: Developers of training focus on initial use and best practices.

45.2 Organizational Experiences in the Late Twentieth Century

For an existing organization, a new communication or collaboration system inevitably disrupts established communication channels, information repositories, and formally or informally designated authorities and responsibilities. The assumption that at some future point a more efficient and effective alignment will take shape is an assumption and is often not shared by everyone in the organization.

Reactions to the uncertainty of success take different forms. The role of evangelism is often stressed—encouraging people to suspend doubts and make a sincere effort to bring the organization to the

promised land. At the other extreme is resistance, either complete opposition or an effort to limit or slow the deployment. Resistance can surface before or after a decision to adopt. In some circumstances, a full embrace or strong avoidance might be rewarded, but another option is to be as informed as possible to seek convincing evidence that there will be a productivity benefit—a measurable return on investment (but see the following caveats)—and identify best practices. When possible, it makes sense to mirror the practices of similar organizations that had a good outcome.

Two complications surface regularly in studies of organizational adoption. Diverging views of organizational stakeholders can be critical for a communication or collaboration technology intended for broad use. Opinions vary based on differences in personality, preferences, or past experiences, but there is a more systematic source of differences, based on the nature of different roles people occupy. The next section introduces Henry Mintzberg's framework of organizational parts, a wonderful aid in understanding studies of technology adoption. Mintzberg argues that almost all large or midsize organizations have several specific parts. Each part has a different structure. A new tool or process is viewed differently depending on where one sits. Failure to appreciate these differences and their consequences creates confusion and impedes adoption.

The second complication arises from the desire to minimize risk by focusing, often obsessively, on metrics and claims for a "return on investment." Proving a productivity benefit is a seductive goal for marketers and acquisition managers, but benefits are often impossible to prove or disprove, especially for communication and collaboration tools that are secondary to organizational production. A desperate quest for "return on investment" often leads to accepting hyperbolic claims and laboratory study outcomes that do not generalize to real-world situations. Joseph McGrath, a leader in research into team and group behavior, produced a framework for thinking about group activities that can widen our lens to bring into view a range of issues that are missed when we focus narrowly on performance.

45.2.1 E-Mail

E-mail is not a new digital communication technology, but a review of its reception by organizations helps motivate our consideration of the Mintzberg and McGrath frameworks.

Multitasking operating systems led to e-mail and real-time chat among users of the same machine. The top-down ARPANET and the grassroots unix-to-unix copy network (UUCPNET) appeared in the 1970s. In the 1980s, commercial e-mail arrived: IBM PROFS and various minicomputer office systems, followed by client–server networks of PCs and workstations.

Acquiring and managing an e-mail system was expensive, but even when in place, organizational acceptance was slow. In late 1983, my manager at a large minicomputer company advised me to ignore the e-mail system and write a formal paper memo, saying "e-mail is a way students waste time." Productivity benefits from e-mail use could never be proven. In the 1990s, leading analysts still argued that organizations would abandon e-mail once they understood the negative effects it had on productivity (Pickering and King, 1992).

Wasted time and the loss of confidential information were concerns. Some companies with internal e-mail systems blocked Internet access and restricted communication to work-related exchanges. Internet access was restricted until December 1995 at Microsoft. Even later, IBM considered it a bold step: "In 1997, IBM recommended that its employees get out onto the Net—at a time when many companies were seeking to restrict their employees' Internet access" (Snell, 2005).

Why was management skeptical? The anthropologist Constance Perin (1991) noted that e-mail was useful for individual contributors (ICs) who rely on rapid information exchange, but problematic for managers who must deal with security issues, rapid rumor propagation, and circumvention of hierarchy. Few managers then had keyboard skills, and interrupt-driven e-mail was not as useful for managers whose time was tightly structured and who dealt with formal documents more than informal discussion. Managerial resistance faced when the cost came down, familiarity based on home use rose, but most crucially, in the 1990s, it became possible to routinely send attachments—the documents,

spreadsheets, and slide decks that are the lifeblood of managers. In some industries, management may yet rely on paper, but for much of the world, e-mail is mission-critical. Concerns about e-mail overload have led some enterprises to experiment with avoiding it, but its value is generally unquestioned. Employees use it to work more efficiently and effectively more than to waste time.

45.2.1.1 Assessing the E-Mail Experience

Most of the technologies we will examine reflect this e-mail progression:

1. Initial use by students and consumers, especially in North America
2. Resistance by organizations skeptical of productivity benefits
3. Young employees familiar with the technology see positive organizational uses
4. Organizational acceptance and adoption grows

Organizational resistance is not always irrational. There is a cost, a learning curve, and a disruption of the existing balance of communication channels, information repositories, and responsibilities. Utility varies across the organization, and benefits that are realized are not always those initially envisioned.

Passage of time has increased the speed with which a new technology can spread. Tools today cost less to introduce. Technophobia is gone. Executives and managers are hands-on users of technology at home and at work.

E-mail needed a quarter century to be widely embraced by organizations. Differential utility to people in different roles and the difficulty of proving an effect on productivity impeded adoption. Now we will consider this experience from the perspectives of Henry Mintzberg and Joseph McGrath.

45.2.2 Mintzberg's Typology of Parts

Henry Mintzberg's (1984) partitioning of an organization is shown in Figure 45.1. Executives (strategic apex), managers (middle line), ICs (operating core), the people formulating work processes (technostructure), and the support staff (everyone else) typically have different approaches, constraints, opportunities for action, and priorities.

Mintzberg observes that organizations can be grouped into five organizational forms, each marked by strong influence by a different part of the organization. In a start-up, the executives control directly; in a divisionalized company, middle management is empowered; in a professional bureaucracy such as a university or surgical ward of a hospital, the operating core (faculty, surgeons) has considerable

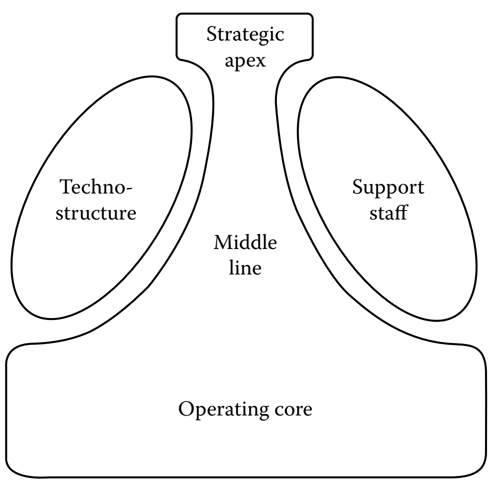

FIGURE 45.1 Five organizational parts.

authority; and so on. In addition, each part of an organization favors a distinct approach to collaboration and coordination: direct supervision (strategic apex), standardization of outputs (middle managers would like to be given a goal and left free to decide how to reach it), standardization of skills (faculty or doctors are certified and then assume they need not be strictly supervised), standardization of work processes (the focus of the technostructure), and mutual adjustment, in which all employees work out their contributions, the approach favored by people in support roles in organizations such as film companies that rely on them. Mintzberg's elegant framework illuminates the different perspectives that come naturally to people in different roles and different parts of an organization. It is no surprise that different features of a technology will appeal to or repel different stakeholders; indeed, this is found in many studies, often overlooked by the researchers, as we will see.

Mintzberg wrote before computers were used for communication and collaboration support in organizations. He did not focus on technology use, but we can extend his model. Consider the three central parts and corresponding roles: ICs, managers, and executives. They differ in the nature of their function and primary activities, their ability to delegate, and the sensitivity of their activities.

ICs who make up the operating core typically engage heavily in communication and are collocated to facilitate this. Managers focus more on sharing structured information—usually documents, which today include spreadsheets and slide decks. Executives of course also communicate and share information, but their primary job is to coordinate the activity of different groups. Communication, information sharing, and coordination—distinct emphases that affect their visions of what a new general-purpose technology will deliver.

Executives' calendars are heavily scheduled far into the future. Managers also have a lot of meetings. Most individual contributors are shielded from meetings so they can produce something—products, services, or documents for use by management.

The ability to delegate work correlates with one's level in the organization. Executives are more likely today to be hands-on users of a technology, but they may not use it long before assigning the task to a subordinate. Managers can delegate some work. The sensitivity to public disclosure of one's work activity also varies. What an IC does is often accessible to others in the organization, whereas an executive's meetings can be highly sensitive. Managers are in between—sensitivities trade off with the benefits in efficiency that can result when their peers know their availability and focus.

In sum, members of these three groups have different structures to their workdays, which impacts tool use. Differences affecting the technostructure and support staff have not been explored as thoroughly. Engaged in defining and improving work processes, technostructure members may advocate for the use of formal workflow systems that promise metrics. The difficulty of representing work activities in software with sufficient flexibility to accommodate exceptions that arise can create tension. IT professionals, members of the support staff, manifest yet another pattern of tool use and often focus on security and reliability, sometimes to the point of obstructing other employees' work.

In retrospect, many efforts to introduce technology are impeded or blocked by not anticipating or recognizing these differences. In Orlikowski's (1992) study of the deployment of the Lotus Notes shared workspace platform in a major consulting company, the strategic apex (senior partners) saw the potential benefits. The operating core (consultants) saw only drawbacks and did not use the system. The IT personnel deploying the system (support staff) had a different incentive structure and used the system very effectively.

Similarly, studies of shared calendar adoption showed sharp disagreements over features among executives, managers, and ICs (Palen, 1998; Palen and Grudin, 2002). When early desktop videoconferencing systems were installed in executive offices, the "direct-dial" calling that they required conflicted with admin-assisted executive meeting initiation (Poltrock and Grudin, 1995). In a study of web use recounted by Jones et al. (2001), the top managers unlike others delegated all save cursory web searching. Understanding this could inspire the design of features to support executive use. These and other examples are covered in more detail in Grudin (2004a,b).

TABLE 45.1 Functions and Modes of Team Activity

	Production	Group Well-Being	Member Support
Inception	Production demand and opportunity	Interaction demand and opportunity	Inclusion demand opportunity
Problem solving	Technical problem solving	Role network definition	Position and status achievements
Conflict resolution	Policy resolution	Power and payoff distribution	Contribution payoff distribution
Execution	Performance	Interaction	Participation

45.2.3 McGrath's Typology of Group Activities

McGrath (1991) described team behavior in terms of three functions and four modes (Table 45.1). Of particular interest are the functions, the columns. Production is the core driver of activity, the reason the group came together. But McGrath placed activities to promote group health and to ensure members get what they need at the same level, arguing they are necessary and in fact continually engaged in. They may go unnoticed—as social animals, we unconsciously attend to them, although not always adequately. The rows in Table 45.1 represent the modes in which a group may find itself at different times—taking on a new task, executing, and occasionally focusing on solving problems or resolving conflicts.

This typology may seem evident, yet it can be a revelation—because our attention is focused almost exclusively on the lower left cell, performance, the production function in execution mode. Management focuses on this cell. Researchers study it in the lab. The quest to show a *return on investment* is perpetual and can lead to narrow, short-term assessments of productivity.

Mysteries are solved by recognizing this myopic focus on performance. Why do some systems do well in lab studies but bomb in organizational settings? Why are others that show no effect in the lab embraced in practice? Dennis and Reinicke (2004) found that insufficient support for group and member well-being explains the lack of commercial success of "group support systems" despite their proven performance benefits in controlled studies. Anonymous brainstorming may work well in the lab, but in an enterprise setting, the identity of a speaker may be crucial, and credit for contributions may motivate participants. Another example is video. It showed no performance advantage over audio in decades of studies, but when other cells of McGrath's framework were examined, video was found to have significant effects in problem-solving and conflict-resolution tasks (Williams, 1997; Veinott et al., 2001). In addition, participants liked video. Greater positive affect could over time contribute to performance in subtle ways.

45.2.4 Reframing the E-Mail Experience

In an organization, e-mail is rarely a prime focus of work. It is used intermittently to support the central tasks. How can one measure the overall impact of getting an occasional quick answer to a question? Does a higher frequency of interaction improve a group's health? How much? How do we measure the effect on performance? Yet unless we believe that eventually a performance improvement will be realized, how do we justify the disruption and unknown outcome of adopting a new communication tool? Those resisting change can make a case.

The two frameworks provide a different perspective on the remark that "e-mail is a way students waste time." That perspective had support from the beginning. The ARPANET was planned as a file-sharing system, a natural vision for managers. E-mail became the tail that wagged the dog, a natural outcome for the ICs in different locations who had to keep the system running and were often its principal users.

A student's principal "production task" may be to learn, but a close second can be building and maintaining social networks that aid in studies and in reaching other career and life goals. E-mail supports activities that serve each of McGrath's functions. Bringing in Mintzberg, informal communication serves students—and ICs in organizations. Managers, not unlike instructors, rely more on formal communication and structured documents. What they perceive as wasted time might not be.

I observed a computer game on a public machine become popular in a competitive group comprising software engineers and a few often-marginalized employees in support roles—usability engineer and technical writer. The top 10 scores were displayed. The usability engineer began playing, culminating in a 16 h stretch during which he achieved by far the highest score. A waste of time? The respect he earned from the software engineers increased his influence. Playing the game may have yielded the highest return of anything he undertook that year. Employees can waste time, of course, but assessing what is ultimately productive is inevitably a judgment call.

45.2.5 Typologies as Guidance

Typologies are not theories, they are frameworks. They emphasize certain features. The test of a typology is whether or not it is useful. These typologies can be used as lenses for understanding empirical phenomena. Examples include those noted earlier and discussed later. Another use is as a checklist for a design or acquisition team, which can consider a system's impact or lack thereof on groups and activities represented by different cells in the typologies. Weiseth et al. (2006) constructed a comprehensive organizational process and technology framework drawing on these typologies. Their framework is centered on models of content, content lifecycle, and process integration. They identify 13 distinct activities in support of coordination, decision-making, or production, each a potential focus of technology support. They identify physical workspace, digital devices, and portals as technological components that bear consideration.

I emphasize that a challenge facing the use of these approaches is the difficulty of proving effects on productivity. When marketing a system, or when considering acquisition and deployment and the cost in terms of adjustment, there is an irresistible impulse to ask for evidence of productivity benefit. Those who claim that they can measure benefits are very popular, but the claims are often not well-founded. Effects, positive or negative, are often subtle.

45.3 A Decade of New Communication Tools in the Enterprise

For decades, as computer use spread, e-mail and bulletin boards or newsgroups were the primary digital communication tools. There were also some chat programs, and information sharing was supported by file-sharing systems built on the evolving file transfer protocol (FTP).

Prior to 2000, most groups—professional colleagues, a set of customers, hobbyists, classroom parents, a housing association, and so forth—could not assume all members were accessible via the Internet. As this changed and more groups become reliably connected, prospects improved for tools to support communication and information sharing. (I do not know of systematic studies, but a critical mass hit my community in the late 2000s—schools and other groups suddenly assumed parents and others had e-mail access, with telephone backup for emergencies.)

The tools that arrived included instant messaging (IM), text messaging, wikis, blogs, microblogs, photosharing sites, geolocation, and a range of social networking sites. Digital voice was built on the conventions of analog telephony; digital video reached and then surpassed familiar capabilities of analog video; the others for the most part broke new ground.

Widely adopted by students and consumers, most of these technologies generally crept into organizations under the radar of management and IT staff. IM and text messaging prospered among consumers

in the late 1990s. After 2001, like a phoenix rising from the ashes of the Internet bubble, diverse new communication and information-sharing technologies were embraced. People had acquired technology and sought things to do with it. Wiki and weblog concepts dated back to the late 1990s, but significant levels of use appeared later.

45.3.1 Instant Messaging and Text Messaging

Basic messaging functionality dated to the early days of multitasking, but widespread use on the Internet arrived with clients such as ICQ (in 1996), AOL Instant Messenger (1997), Yahoo! Pager (1998), and Microsoft's MSN Messenger (1999). Text messaging had a similar history with a notable twist. Experiments in the early 1990s followed the advent of 2G cellular technology, but use mushroomed only after telecoms had worked out billing systems in the late. The twist was geographic: The other technologies discussed in this chapter reached prominence first in the United States, with most software and platforms developed there. Text messaging ran on mobile phones produced mainly in Europe and Asia; low messaging costs were set there and use followed.

By 2001, half of all U.S. Internet users, 60 million, had adopted IM. Many of them were part of the workforce, but IM (and text messaging) was overwhelmingly used by students and consumers. Contact lists comprised family and friends.

That said, IM clients were easily downloaded onto computers in most workplaces. IM slowly came into focus in organizational IT departments. In late 2001, an IM client intended for organizational use—no winks or emoticons—was included in Windows XP. Consulting companies began advising organizations on IM use. The advice might be summarized, "IM is a way students waste time." The expressions, "productivity drain," "communication quagmire," "worse than e-mail overload," "no data security," and "no enterprise management" appeared in Gartner reports over the next few years (Lovejoy and Grudin, 2003). Professional IM client uptake was not strong. Many employees were using IM, but did not want a second client, and those not using one for personal communication did not flock to adopt one for workplace use.

Table 45.2 lists the similarities between IM in the mid-2000s and e-mail 20 years earlier. In the 1980s, no directory of e-mail addresses existed, and addresses were highly unpredictable; people could contact acquaintances. Memory was too expensive to save e-mail messages, so it was an ephemeral, informal channel. All of that changed. Young people interviewed 20 years later praised IM and text messaging for being "informal, unlike e-mail." E-mail was by then routinely saved and used in court cases

TABLE 45.2 Parallels between E-mail and Instant Messaging

Email in 1983 ***and 2003***	IM in 2003 ***Was Evolving***
Used mostly by students	Used mostly by students
Used by everyone	***Use spreading rapidly***
Access limited to friends	Access limited to friends
Accessible to everyone	***Pressure to remove limits***
Clients not interoperable	Clients not interoperable
Complete interoperability	***Pressure for interoperability***
Conversations ephemeral	Conversations ephemeral
Conversations saved	***Recording is more common***
Chosen for informality	Chosen for informality
Became the formal option	***Becoming more formal***
Organizational distrust:	Organizational distrust:
Chit-chat? ROI?	Chit-chat? ROI?
Mission-critical technology	***Becoming more routine***

and government inquiries. A decade later, text messages are saved and appear in court cases; not quite formal, but moving down the same path.

Organizational use of IM built up under the radar. In 2003, a company marketing tools described an effective approach: Ask IT managers how much their employees used IM at work. The reply was often "none." They then installed measurement tools that revealed significant use of downloaded IM clients. They claimed that IT managers often then became interested in tools to monitor and control IM use (personal communication).

Workplace uses of IM were a major focus in studies of communication tools conducted in 2004 (Grudin et al., 2005). Use for quick questions and answers was reported by over 90% of IM users; for socializing by 43%. Many noted that IM was less expensive than the phone when on the road. Others used it during phone calls, teleconferences, and meetings—to get relevant information from people not present, to hold private conversations with others in the meeting, or to forward information to everyone present without interrupting the conversation. Some managers were as heavy IM users as ICs; for example, using it to do other work when in a large meeting that was focused on issues not relevant to them.

Other workplace uses addressed work–life balance issues. E-mail is less intrusive and therefore relied on to organize a school band concert or field trip, but when the event is imminent and quick responses are needed, work interruptions are tolerated and organizers sometimes shift temporarily to IM. In another example, a woman kept an IM window open on her computer at work so she could see from a status change that her son was safely home from school, since his first activity was to get on IM to interact with friends. Prior to using IM, she had interrupted work to telephone to confirm that he made it home.

Could the cumulative impact on productivity of these discrete, relatively low-frequency activities be measured? Laboratory studies do not reliably generalize to the low-frequency use typically found in workplaces. Yes, a quick answer to a question could be significant, but would not other channels have served equally well?

The IM client feature used most after messaging was file sharing. It took decades to fully integrate attachments into e-mail; its early presence in IM facilitated adoption in work settings.

Nevertheless, by the time IM was widely used in organizations, students and consumers were moving to web-based software.

45.3.1.1 Critical Mass Requirements for New Social Media

Web-based social media differ in terms of the scale of participation. A blog requires one author and an audience of variable size. A wiki requires group participation, but the group can be small. A social networking site such as MySpace, Facebook, LinkedIn, or Twitter requires larger numbers of participants to be effective. More specialized sites such as Foursquare and Pinterest require large scale with a narrower focus. These came into prominence in roughly that sequence.

45.3.2 Corporate or Employee Blogs

The term weblog was coined in 1997. The LiveJournal and Pyra Labs Blogger platforms appeared in 1999. By 2002, how-to-blog books were in bookstores. Visibility picked up in 2003 when Google bought Blogger, Wordpress was released, and LiveJournal hosted its millionth blog.

In late 2004, *Communications of the ACM* published a special issue on "the blogosphere." Bloggers were mostly teenagers or in their early 20s, maintaining online diaries on LiveJournal and elsewhere to be read by friends or family. A smaller but significant set of blogs sought larger readerships: essays or pronouncements on technology and other subjects by journalists, pundits, political candidates, and entrepreneurs. Some of the latter hesitated to call the former "bloggers," but some personal blogs were indexed by search engines and evolved to wider readership, whereas some pundits failed to find

many readers. Early research examined both student blogs (e.g., Nardi et al., 2004) and the elite or "A-list" blogs (Bar-Ilan, 2004).

Technorati has published "state of the blogosphere" reports since 2004 (http://technorati.com/state-of-the-blogosphere/). "Corporate blog" initially referred to any whose author was clearly linked to an organization. Many were employees blogging about their work and lives. Today, a "corporate blog" is one authored by one or more people whose principal job responsibility is to blog on behalf of an organization. In this chapter, "employee blog" is used as a general term.

In late 2004, Technorati was tracking four million blogs, which produced four posts per second around the clock. Five thousand, one in 800, were employee blogs. Measurable numbers were from employees of companies such as Oracle, SAP, and Sun. Others were from companies marketing blogging tools and from mainstream media sites. These were more likely to include people paid to blog. The organization with the most employee bloggers identified by Technorati was Microsoft, which had close to 1000 or one-fifth of the world total.

In 2005, IBM formally encouraged its much larger employee population to blog publicly (Snell, 2005) and the picture changed. Gartner forecast that corporate blogging was losing its "hype" status and would be mainstream within 2 years.

A study conducted in the summer of 2005 identified complex reactions to the introduction of employee blogging at Microsoft (Efimova and Grudin, 2008) and is the basis for the case study that follows. Microsoft and IBM are not typical organizations, of course; many discourage most or all employees from blogging externally. However, many of the observations resonate with other accounts.

45.3.2.1 Case Study: Microsoft Adopts External Blogging (2003–2005)

Students with externally hosted weblogs, hired as interns or employees in 2000–2001, were the first Microsoft bloggers. They attracted negligible attention. By mid-2002, some employees manually hosted personal weblogs on their work machines.

There are three possibilities for employee blogging, two for externally facing blogs and one for internal blogs. By using a web-based blogging platform, any employee could manage an externally facing blog from his or her work computer. If a company is willing to dedicate a server to host external weblogs, it can facilitate, promote, and monitor employee blogging. It also makes it much easier for external readers to find a relevant employee blog—"one-stop shopping," at least for blogs on the server. Finally, a blog visible only inside the firewall would require an internal blog server.

Grassroots efforts by passionate employees to establish servers eventually brought blogs to the attention of low-level managers. An internal weblog server, maintained on an unused machine through volunteer efforts, hosted a few dozen weblogs by the end of 2002. Late in 2002, a list of externally visible employee weblogs was published by someone outside the organization. This helped create a sense of a community engaged in externally visible blogging. It also brought blogging to the attention of people in the company's legal and public relations groups for the first time. The subsequent meetings and reflection on practices led to some tensions but no actions.

By mid-2003, a server hosting externally visible weblogs was operating with budget support from a manager who perceived a benefit in using weblogs to communicate with customers. However, the company is decentralized enough that the wisdom of letting employees' blog was still being actively debated.

Blogging was still very much below most radar screens. In April 2003, one author came across a disgruntled employee's blog written for friends in which he described actions that would be grounds for termination. Later that year, a contractor was dismissed for a relatively minor disclosure in a blog. Many in the weblog community had made similar disclosures. This fed a sense that legal and public relations representatives who in meetings said "consult us when in doubt" wanted to shut blogging down. Mainstream media reported a Google employee fired for blogging about everyday life at work, and blog-related dismissals at Delta Airlines, ESPN, and elsewhere (e.g., Cone, 2005). IBM's public embrace of external employee blogging was still 18 months in the future.

Discussions among bloggers, human resources, legal, and public relations that followed the dismissal were regarded as mutually educational. Blogging picked up, leading to the 2004 Technorati report, but debate continued. A senior vice president had begun blogging in May 2003, and Bill Gates and Steve Ballmer spoke of blogging approvingly (Dudley, 2004). But another senior vice president in 2005 castigated bloggers as "self-appointed spokespeople" for projects, products, and the company.

By the summer of 2005, unofficial lists of employee bloggers for Amazon, Google, IBM, Sun, and other companies were on the web. Microsoft IT administrators responsible for two externally visible servers that carried 2,000 blogs estimated that 3,000 of the 60,000 employees were active, but a reliable employee survey found over 7,000 blogs, many hosted on web platforms. Some felt that external hosting promoted a perception of independence and gave them ownership of their writing. The internal server was still largely unmonitored and volunteer-run, to the disappointment of the 800 internal bloggers.

In interviews, senior attorneys and publication relations managers described a shift in attitude. Previously skeptical, they now saw value in employees connecting with developers, users, and others outside the company. Bloggers provided useful support and put a human face on the company. Two attorneys said that the 2003 contractor offense would no longer result in a punitive reaction. Avoiding disclosing of sensitive information was not a new concern; a blog might have a faster or broader impact than e-mail or a newsgroup post, but the rules were the same. Similarly, a senior public relations manager described his group's highly sophisticated approach to modeling how blogs, press releases, and the mainstream media interacted. Their goal had become to get in front of and work with employee blogging, not to suppress it.

Bloggers could be a source of joy or stress for middle managers. Many employees cleared their intention to blog with their direct manager, who knew and trusted them, but worried that higher-level managers would not approve. Tensions could arise when an employee's blog about a product or team effort developed a large external following. An employee might seek more time for blogging, irritate less visible but equally productive team members, lobby for changes by suggesting them in a visible forum, and create issues by taking a new position inside or outside the company, or otherwise discontinuing their blog.

Managers also had to assess whether time was being used productively. Bloggers who set out to post only about professional issues discovered that an occasional personal item led to a positive reader response. Authors believed it made them more effective; managers had to justify non-work-related posting in a company that had some skeptics in upper management.

An intense quest for metrics to assess the value of employee blogging did not get far. Employees who would never write a formal article for the company website blogged to provide information, share tips, and engage in discussions with customers or partners. But how is this value measured? Blogs humanized the organization, an intangible asset. Blogs were used to document and organize work. Employees reported following external blogs and discovering colleagues and ideas that they had not encountered by internal communication—again, how does one attach a numerical value to this?

In mid-2005, a few people were assigned to blog. Groups were experimenting with approaches to willfully creating a team or product blog, often contributed to and sometimes written by multiple people, with or without bylines. All involved editing, in some cases casual, in others more formal. Everyone recognized that immediacy and informality were keys to effective use of this medium.

It was at this time that IBM publicly encouraged its employees to blog, which helped validate the medium at Microsoft as well. Some full-time bloggers appeared, focused on image, marketing, and public relations.

In subsequent years, blogging has become more professional, regularly featured in newspapers. Multiauthored blogs are more prevalent. In some respects, blogs have been absorbed into the broader authored digital media, a little more spontaneous and unedited. Bloggers surveyed by Technorati aged. LiveJournal faded away. Although millions of blogs are active, focused on hobbies and other activities, the sense of immediacy passed to social network sites and microblogging (Twitter), discussed later.

45.3.3 Wiki Use in Organizations

Wikis are more constructional than conversational. The content of IM and text messages, blogs, and social network posts generally recedes untouched into the past; most wiki content is there to be edited. That said, wikis often contain conversational sections, social network sites blend persistent and conversational information, and generally there is a move toward hybrid applications.

A major organizational use of wikis is internal, as a dynamic information repository for project management or to communicate across groups. Wikis are also designed for interacting with partners, customers, or vendors (e.g., Wagner and Majchrzak, 2007). Finally, employees make use of Wikipedia and other public wikis. Published research into this is limited, but given that attorneys cite Wikipedia in legal articles and judicial opinions (People, 2009) and physicians consult it (Hughes, 2009), we can assume use is highly widespread.

Most published wiki research examines Wikipedia, followed by public wikis. Neither is the focus here, nor will findings generalize. Wikipedia is a special case, and any wiki on the web has about one million times as many potential viewers as a large organizational wiki. Vandalism is a major concern for public wikis but not inside a firewall. Information accuracy is a major issue for public wikis; in organizations, it plays out differently, focused mainly on staleness. Organizational wiki users typically also communicate via other channels (e-mail, face to face, etc.), whereas most Wikipedia discussion occurs through the tool itself. The "Academic Studies of Wikipedia" page in Wikipedia is a good starting point for those interested in that topic.

Another major focus of wiki research is on classroom use. Classes are about finding, organizing, and sharing knowledge. Students are often open to new tools. Nevertheless, results are mixed; educational institutions have routines that can create conflicts, notably around assessment (Forte, 2009). Virtually all classroom wikis are short duration, lasting one term. Classrooms bear some resemblance to start-up companies, but on the whole, they are not models for enterprise use.

Poole and Grudin (2010) classified organizational wikis. Our principal focus is on one category: topical or project-specific wikis contributed by multiple employees. A second category comprises "pedias" that span an entire organization, modeled on Wikipedia. They first appeared around 2005 when Wikipedia's success became evident. Most prominent in the media was Intellipedia, piloted in 2005 by the U.S. intelligence community and launched in 2006. MITREpedia, Pfizerpedia, and others followed. Careful studies have not been published, and recent years have seen little mass media attention to pedias (other than Wikipedia). The third wiki category comprises what are effectively personal intranet web pages. These are often started by an individual hoping to attract other contributors; when they do not materialize, either the wiki dies or the founder continues it as a solo endeavor, posting information deemed useful.

Published wiki research favors surveys of wiki users and papers written by wiki developers or evangelists in early stages of engagement. Majchrzak et al. (2006) received 165 survey responses from wiki-oriented listserv participants who felt wikis are sustainable and work better when directed at novel solutions or managed by credible sources. Interviews based on small numbers of participants and single sites identified problems familiar from earlier knowledge management system implementations: lack of management support, data that are obsolete or difficult to find, and usability problems (Ding et al., 2007; White and Lutters, 2007).

Egli and Sommerlad (2009) is an upbeat but objective report of a law firm's implementation of a wiki to support collaboration, information display, and personal use. Challenges they identified are covered later.

Phuwanartnurak (2009) describes wiki use in two short-term university IT department projects involving young, mostly wiki-savvy developers. The tool was used, though some disliked the slow updating and preferred IM for communication. This resembles the use of wikis in start-ups, also discussed later.

In a mixed survey and interview study covering thousands of wikis in several organizations, Grudin and Poole (2010) found that the vast majority of wikis were abandoned, often early. Many others never

attracted a second contributor and became personal web pages on the intranet. Factors leading to abandonment and conditions conducive to success are discussed next.

With public wikis including Wikipedia, the bottom-up zeitgeist has meant that administrative structures, quality control practices, and reputation and incentive systems have emerged and evolved over time in response to the environment. The organization and reorganization of information also occur over time. Discussions happen through the wiki. This organic, self-contained process has slim chances of surviving the force fields of a dynamic organization.

Most organizations already have administrative structures, people responsible for certain topics, quality control processes, incentive and reputation systems, information repositories, and established communication channels. The existing structures cannot be grafted onto the wiki. If a known authority does not participate, others may be uncertain how to proceed. An employee may feel uncertain about editing the contribution of a senior person, whether or not that person encourages it. Should material in repositories elsewhere be duplicated in the wiki? Should communication happen in the wiki, in e-mail or distribution lists, or by convening meetings? Decisions on such matters do not bubble up and often remain unresolved.

Small start-ups are a sharp contrast. Lines of authority are ill-defined; everyone pitches in when they can. Employees are often younger, tech-savvy, and ready to try anything. There are few firmly established repositories, authorities, or communication channels. Literature cited earlier supports start-up ventures as promising for wiki use. Grudin and Poole (2010) reported successful wiki use in three start-ups—and also in two start-up-like efforts within a major corporation.

Information organization in a wiki is flexible when it is created, but often difficult to adjust later when information needs become better understood or change. Also, the formatting of content is often inflexible. These are sources of wiki abandonment. Changing a wiki in response to a group division or merger can be very difficult, as can the extraction of information for other uses. Wikis that use a global namespace hinder extension. Broken links and information that is obsolete or difficult to find are chronic problems. As with other file systems or document repositories, structure is critical, and the requirements are often not knowable or carefully worked out when a wiki is created.

Another major issue derives from Mintzberg: Even when they all agree the wiki will be a wonderful critter, executives, managers, and ICs have different views of exactly what it will be. Executives may envision the end of the elusive knowledge management quest to capture the knowledge or retiring employees for reuse by others. (This will not happen.) Managers may anticipate a "project dashboard" maintained by their team. (This is unlikely as well.) ICs may approach it as a resource for ad hoc problem solving, posting answers to frequently asked questions and other information useful to people like themselves. (This is the most likely success, if disillusioned executives and managers do not pull the plug.) Grudin and Poole (2010) found that enthusiasm could be strong at the top and bottom of organizations, with managers caught in the middle, trying to deal with the inevitable disruptions accompanying a new system.

Danis and Singer (2008) describe a 2-year-old enterprise wiki that had an exceptionally strong design team. It also benefited from an executive who was a strong proponent and no alternative to adoption: It replaced a system that was removed. The wiki was designed and deployed by an IBM research group for use in an annual project proposal review. The executive envisioned it being used year-round, but this did not materialize, and when he later retired, the wiki was retired as well (personal communication). Early stages in the migration of a document repository to a wiki are also described in Alquier et al. (2009).

45.3.4 Social Networking at Work

A decade after they began to attract notice, web-based social networking sites are being used by over 15% of the world's population. The prominent initial public offerings (IPOs) of LinkedIn and Facebook signal that social networking is considered reasonably mature. Their use by politicians, entertainers, and athletes helps legitimate them to organizations, which in any case have more difficulty keeping their use out than bringing it in.

Early terminal-based computers and the early Internet supported social activity. From 1995 to 1997, ICQ and AOL Instant Messenger were released and phone-based text messaging ramped up, acquainting more people with buddy lists and real-time or quasi-real-time digital communication. Classmates.com and Six Degrees were early efforts to use the web to provide a persistent device-independent online home for social activity.

Activity increased substantially 5 years later; perhaps the Internet bubble had to grow and burst, leaving many more people online and looking for something to do there. From 2002 to 2004, Cyworld, Friendster, Plaxo, Reunion.com, Hi5, LinkedIn, MySpace, Orkut, Facebook, and Microsoft Live Spaces were released and actively promoted. Different sites became prominent in different regions.

By 2013, the field has shaken out. Facebook, LinkedIn, and Twitter (which appeared in 2006) dominate outside China. Specialized new sites include Foursquare, Pinterest, Instagram, and Google+. Yammer is a prominent vendor of social networking that keeps exchanges within a corporate firewall. It was acquired by Microsoft in 2012.

Early use by students: Students were enthusiastic early adopters. Academic achievement and socializing are key student activities and social networking sites help with at least one of these. Students tend to start with less complex social networks, and early clients were not complex.

Colorful and chaotic MySpace was once the most active site. Studies of high school and college students (Hargitai, 2007; Boyd, 2008) found that students aiming at professional occupations tended to consider MySpace gaudy and not serious. Use declined in favor of Facebook.

Facebook famously began on college campuses. Student Facebook networks initially resembled IM or SMS buddy lists (Lampe et al., 2006, 2008). Many students felt faculty should be excluded, with women particularly concerned about privacy (Hewitt and Forte, 2006; Fogel and Nemad, 2009). Over time, fewer students allowed open access to their Facebook profiles, with women reporting more use of access control and long-time users less concerned (Tufekci, 2012). Attitudes to privacy depended on whether students networked primarily to communicate with existing friends or to find people with common interests.

Facebook was made available in anticipation-generating waves to elite universities, other universities, and high schools, and in 2006, employees of a few enterprises followed by general availability. When LinkedIn was launched in 2003, it asked for a person's occupation, employer, and past university, which discouraged student use. Its growth was deliberate but steady. It served job seekers, recruiters, and also professionals interested in a free, professional-looking web page and self-updating address book.

Use by the general population: The age, ethnicity, and socioeconomic profiles of the general population of social networking site users differ from most enterprise employee profiles. In addition, most studies rely on surveys of self-selected individuals. Enterprise use contexts differ in other ways; notably, anonymity is common in general web use but not on corporate intranets.

However, some studies of general use foreshadow results found in enterprise settings and discussed later. Naaman et al. (2010) found clusters of Twitter users: Some focused on posting about themselves and their activities, others primarily relaying information. Regrets expressed following Facebook posts remind us that technologies mature through trial and error (Wang et al., 2011). Similarly, flaming was a major topic in early e-mail use.

Media attention tends to focus on potential problems: students posting material they will regret, people fired for postings deemed inappropriate, and possible misuse of personal information by site owners. The growth in popularity of the medium indicates that this has not markedly affected uptake, but it could shape behavior in subtle ways.

Workplace studies: Many studies of enterprise use of social networking address internal systems confined to a company's employees. Most of these are prototype systems built and deployed at IBM, such as Beehive (later called SocialBlue), Blue Twit, Cattail, Dogear, and Timely.

A second set of studies examines employee use of sites such as Facebook, LinkedIn, and Twitter for work (and other) purposes. Some uses are directed outward—recruiting or public relations—and others inward—to build social capital, find answers to nonconfidential questions, and so forth.

Internal prototypes have advantages: With restricted membership, employees can discuss company-confidential information. Researchers can log and analyze use and conduct follow-up interviews. Drawbacks include limited participation—typically a few percent of enthusiastic employees who are willing to invest time in a system likely to be discontinued. This limits the generality of results, even within the enterprise deploying it.

45.3.4.1 Case Study: IBM Beehive (2007–2011)

In 2007, IBM launched a Facebook-like social networking system called Beehive. In 2008 and 2009, 15 papers on different aspects were published, with more to follow. At the time of the first published studies, fewer than 0.1% of IBM employees were using Beehive (DiMicco et al., 2009); toward the end 17% had profiles (Thom-Santelli et al., 2011), although the final study indicated that fewer than 1% of employees posted once in a 4-week period (Thom et al., 2012). The system was taken offline in early 2012, with some features incorporated into IBM Connections.

Nine months after deployment, employees used Beehive to share personal information, to promote themselves by describing skills and accomplishments, and to campaign for projects (DiMicco et al., 2008). It was not used to find information or get quick answers to questions. In a finding frequently reported, many people initially used it with close colleagues but later found it more useful for establishing weaker ties with other colleagues. They found new contacts through “friends-of-friends” and did not experience privacy concerns. Other popular uses included sharing structured lists (Geyer et al., 2008a).

Several efforts aimed to increase participation. A ratings-based incentive system had a short-term effect (Farzan et al., 2008, 2009); removing it had a strong negative effect (Thom et al., 2012). Recommender systems were explored in efforts to (1) increase participation by recommending expansion of profile information (Geyer et al., 2008b), (2) identify and suggest new contacts (Chen et al., 2009; Guy et al., 2009; Daly et al., 2010); (3) increase engagement (Freyne et al., 2009), and (4) direct people to items of interest (Freyne et al., 2010). More profile information correlated with more contacts (Dugan et al., 2008). An interesting finding was that personal network structures could be inferred more effectively from outward-facing social network information than from relatively private e-mail thread data (Guy et al., 2008).

A major theme was the use of Beehive to build social capital (Steinfield et al., 2009; Wu et al., 2010). There was evidence of utility for organizational acculturation (Thom-Santelli et al., 2011), though communication was largely within geographical region (Thom-Santelli et al., 2010). Employees expressed the wish that Beehive was integrated with other social networking sites (e.g., Facebook).

In early 2009, Zhang et al. (2010) studied one organization’s use of Yammer, the Twitter-like tool for internal corporate use (with less constrained post length) launched in 2008. Yammer was used by 1.5% of employees to broadcast group or business unit status, ask and answer questions, send directed messages for real-time interaction, relay items of interest, and follow individual posters. Hashtag use to identify topic was rare. Almost all users were over 30 years old; about a quarter were also active Twitter users. With such limited adoption, even enthusiastic users had difficulty finding value.

Yammer reports use by employees of 200,000 companies, including over 400 of the Fortune 500, with around 4 million users or about 20 employees per company on average (http://www.yammer.com, 10/5/2012). It remains unclear how social networking inside a firewall will fare.

Higher uptake of internally developed social networking systems such as D Street at Deloitte is reported in the press. A complex social business platform at MITRE was the focus of a well-executed study employing logs, surveys, and interviews after 2 years of use (Holtzblatt et al., 2012). The Handshake system includes blog, wiki, file sharing, and social network features. Of the 60% of employees who tried it, benefits were largely reaped by the 18% who used it actively. Benefits were attributed to standard social networking features, the integration of capabilities that include heavier-weight collaboration around documents, and

the ability to create groups that span the firewall to include customers. Focusing more on organizational and technical challenges, Rooksby and Sommerville (2012) describe internal and public site use in a large government agency. The appropriateness and risks of accessing public sites was a key issue.

Corporate uses of Facebook, Twitter, and LinkedIn: A quarter to a third of companies reportedly ban employee access to external social networking sites from the workplace (e.g., Purdy, 2012). However, employees can circumvent bans using smart phones. As with Internet, e-mail, and web use, prohibition is unlikely to persist. Past experience indicates that employers who can trust employees not to misuse new technologies benefit overall from employee use. Still, employee uncertainty about appropriateness affects behavior, as reported in Rooksby et al. (2012). Lampe et al. (2012), unexpectedly not finding Facebook used by university staff for work-related questions and answers, attributed it to such concerns.

Apart from the Microsoft case study provided later, research into enterprise uses of public social networking sites has focused on early adopters and heavy users. This provides a view of how sites *can* be used and some issues that are encountered but limits the generality of the findings, as does the rapid uptake of these technologies: Every year the landscape changes, with more users, new features and options, and higher levels of experience. Compare studies that were conducted in different years with caution. That said, some trajectories are evident.

In an early study of Facebook use in an enterprise, DiMicco and Millen (2007) identified three categories of Facebook profiles of young professionals moving from college to the workplace: "reliving the college days," comprising personal information, informal status messages, use of the Wall, and nonprofessional images; "dressed to impress," primarily job-related information with some personal information and formal images; and "living in the business world," consisting of limited profiles from new users as opposed to those who first adopted it as students.

Zhao and Rosson (2009) recruited 11 heavy users of Twitter at a large IT company in late 2008, using personal contacts and "snowball" referrals. Anticipating the Yammer findings described earlier, Twitter was used by these enthusiasts for "life updates" or personal status, timely sharing of information with friends or colleagues, and as "personal RSS feeds" to monitor trusted external sources of news.

In early 2009, Ehrlich and Shami (2010) compared Twitter and BlueTwit, a short-lived internal IBM tool that allowed posts of 250 characters. BlueTwit had been adopted by one-third of 1% of all employees. Thirty-four active users of both tools were identified. Fifty-seven percent of their posts were from five users who averaged 18 per day. On BlueTwit, they did less status posting and directed more information and comments to specific individuals than on Twitter. How to generalize from this sample of the 400,000 employees is unclear. A widely publicized Twitter-based event lasting a few days attracted stories conveying the company's culture (Thom and Millen, 2012). Although only about one-fifth of 1% of employees posted stories, it was considered a success.

Surveys of communication at a small company in mid-2008 and mid-2009 found Facebook, LinkedIn, and Twitter use increasing, with weekly use of Facebook and Twitter the norm (Turner et al., 2010). The authors anticipated that use of Twitter would thrive. Voida et al. (2012) is a study of the use of sites to communicate externally; they examined volunteer organizations and found them using sites to raise funds, publicize events, and recruit volunteers, but sites were not useful for volunteer coordinators, whose need was to focus on individuals and build strong ties.

45.3.4.2 Case Study: Cross-Sectional Trend Study of Microsoft (2008–2012)

Each April starting in 2008, a different random sample of 1,000 Microsoft employees (out of about 90,000) was invited to take a survey on communication practices. The survey explored their attitudes toward and behaviors around public social networking sites. Over 40% responded each year; their demographics matched those of the company as a whole. Employees varying in age, gender, role, level, geographic location, attitude toward social networking, and behavior were subsequently interviewed three of the years. Skeels and Grudin (2009) describes the first year, Archambault and Grudin (2012) the first four, and Zhang et al. (under review) the fifth year.

Microsoft is atypical but varied: 45% of the employees are in business groups, 45% are in sales and marketing, and 10% support operations. Almost half are in the Seattle area and the rest are distributed around the world. In 2008, 49% had Facebook profiles and 52% had LinkedIn profiles, the latter used less frequently. By 2012, over 80% of all age groups had Facebook profiles. Over 50% reported being daily users of Facebook, and 20% *daily* users of LinkedIn, primarily in sales and marketing divisions.

In 2008, a major issue was the tensions arising from having contacts from different facets of life or who spanned other boundaries—friends versus coworkers, family members, what do you do when your manager, vice president, or customer asks to be your friend? People tended to use just one site. Access control mechanisms were just appearing. By 2012, use was more sophisticated—people had set up different Facebook groups and used LinkedIn groups, used Facebook pages, and used Facebook, Twitter, and/or LinkedIn differentially. People wanted to be able to scan all their sites in one place; for example, on their phone as they waited in a queue. Concerns about privacy diminished as people felt they were establishing more control over their networks. One finding was that female employees made more use of access control features and expressed fewer concerns about the use of sites than male employees did.

The segmenting of online social worlds is discussed by many researchers, most incisively by Stutzman and Hartzog (2012) who studied a special population: adults with multiple identities on a single site. Although a highly atypical group, why and how their informants differentiated audiences and used their identities is consistent with the observations of Microsoft employees.

Are social networking sites useful for external professional networking? Many employees were unsure in 2008 but by 2012 agreed. For networking within the company, however, even in 2012, 20% disagreed and almost 30% were neutral. In 2008, managers were less likely to see internal utility; by 2011, managers were more likely than ICs to see the potential for internal use. For those seeing social networking as useful, strengthening ties with coworkers was from the start a strong rationale.

By 2011–2012, Facebook use had plateaued at 60% daily use and around 80% occasional use. Twitter use plateaued in 2010 with close to 10% of employees using it daily. Occasional Twitter use continued to grow, reaching 30% so far; people used it to track work-related and personal events and feeds and to publicize work-related developments. In conclusion, social networking was integrated into the personal and work lives of many, who showed no indication that they might abandon it. Instead, they took countermeasures when developments made them uneasy. Despite mass media stories of overload and burnout, social networking appears to be here to stay.

45.4 Discussion

When the Internet bubble burst in 2000 and 2001, it left behind a strong digital infrastructure. Businesses and homes had acquired computers and Internet access. Moore's law was not revoked, so capability grew and prices fell. The communication media discussed in this chapter capitalized on the infrastructure and critical mass of users remaining when loftier ambitions were swept away. This is one interpretation of the timing of the embrace of these innovations, along with Wikipedia, Delicious, Flickr, YouTube, and others.

The pace of experimentation and change is unlikely to be maintained. A vacuum was filled. The technologies are maturing. The high valuations of LinkedIn and Facebook indicate an expectation that they will prosper. Hundreds of millions of users are accumulating years of experience, finding benefits and comfort levels. Most new entries focus on niches—Instagram for pictures, Pinterest for web collages, and Foursquare for location check-in—rather than challenging Facebook in the way it challenged Friendster, Orkut, Bebo, MySpace, and others. Moore's law still has not been revoked. Smaller form factors are more important, but they too extend rather than replace existing practices.

45.4.1 Contagion

An innovation requires a critical mass willing to see through the initial disruption as effective practices are worked out and promulgated. Communication technologies have one advantage: Best practices can be shared through the technology itself.

A student cohort is ideal for a communication technology—a small group that communicates intensely, is young and willing to experiment, and has relatively few external ties and habits. One of the cohorts is excited about the possibilities of a new technology, and friends will give it a try. Start-ups share these qualities—an intense need to communicate, inherently experimental and youthful composition, a focus that blocks out other ties, few habits built up around other channels and repositories, and relatively little hierarchy.

For IM, weblogs, and social networking sites, achieving use was not the challenge. Consumer clients or platforms were quickly adopted. One challenge for enterprises is determining whether to embrace the technologies. If they opt to do so, they must either determine how to make use of the clients and platforms employees are already using, convince employees to shift to or also adopt corporate versions, or find a way to integrate the two.

Wikis are an exception. Most employees, even young ones, are not yet active wiki contributors, so it is a more traditional adoption context. Start-ups are promising candidates for the reasons listed. Adoption in mature organizations requires other approaches to achieving critical mass. A project that resembles a start-up—a new team or new assignments, no existing repositories, and preferred communication channels—is a good candidate.

On a national scale, the breakup of the Soviet bloc unleashed an entrepreneurial ferment among young professionals: ICQ IM and LiveJournal blogs, used overwhelmingly by students in the United States, established a strong presence in eastern European enterprises.

The importance of evangelism and executive backing in spurring adoption is often stressed for large enterprises in relatively individualistic or command-and-control cultures. Use may spread more contagiously in consensus-oriented cultures. This may be why some blogging and mobile technology adoption in Asia transcends age and occupation to a greater extent than in Europe and North America.

These emerging technologies benefited from two external developments. One is the uncertainty that surrounded the rise of the web. An anxious search for business models that would be viable in a digitally connected world opened doors for experimentation. Another is the successful use of the technologies by people in entertainment, government, and crisis situations. Examples are the use of Twitter by Oprah Winfrey, star athletes, and popular entertainers, and the complaints of the Obama team that they could not use familiar communication tools when entering the White House in January 2009—which revealed that they truly relied on these channels. Studies of use of blogging and social networking sites in Middle East crises (e.g., Al-Ani et al., 2012; Starbird and Palen, 2012) are evidence that these tools can be powerful in certain contexts.

45.4.2 Evolution

Over time, three aspects of the information in these channels changed: its formality, its progression from text to multimedia, and the sizes of intended audiences. Each presents a trade-off. Quick, informal information exchange can be useful; in other contexts, organized, formal documents can be essential. Text is economical and often sufficient; photos and other multimedia are engaging. A small targeted group was convenient and may be desirable, but some messages are intended for broad audiences, and we do not always know when and for whom one will be useful.

Information exchanged informally sometimes proves to be useful later, but when communication is routinely saved and could be forwarded, a medium becomes more formal. Spell checkers are added. It is subpoenaed in court cases. E-mail started informally and became formal. IM and text messaging moved into the informal communication niche; now they too are saved and subpoenaed.

For decades, most digital communication was text, but with websites came multimedia. At work as well as home, people love photos. Cell phone buddy lists and IM contacts were initially limited in number, but websites for maintaining lists of contacts and followers changed this.

These factors drove the progression from messaging to social network sites for some purposes: from limited social networks of friends to segmented audiences that can be useful for work. Many early bloggers addressed friends and family only or broadcasted to the public. Enterprises slowly engaged with blogging, internally or externally, seeking large but targeted audiences. Twitter feeds may be impacting heavy-weight corporate blogs, which require more time to construct and read. For most purposes, 140-character announcements of products or events are easier for everyone involved.

45.4.3 Approaches to Organizational Deployment

The single most important consideration when considering a new communication technology intended for wide use is the differing perspectives of ICs and managers. It is not that they are at loggerheads—their desired outcomes are usually shared. They differ in how they work, what will help them, and how they perceive each other working. They have different views of what a tool will do. Understand and address this during design and deployment and the odds of smooth adjustment should improve substantially.

Wikis are a clear example. On the surface, wikis appeal to both groups: Information can be structured and anyone can contribute. In practice, the structures a manager envisions may not align with the content individuals find useful to contribute. Manager and IC interests converge in posting answers to questions frequently asked by new employees streaming into a start-up. In other situations, lack of clear credit and accountability interfere with open editing. If a Wikipedia page has erroneous information, no one's job is on the line, but in an enterprise it can be different.

Executives may believe they know how managers should work and managers may believe they understand ICs, but understanding how a new technology will fit into one's own workflow is hard enough. Imagining it for someone in a different role is beyond reach. If employees can be trusted or lapses detected, letting people find the tools useful to them may be advisable, with high-level modeling, encouragement, and evangelism to get it bootstrapped.

The corollary is that an environment with diverse, interoperable tools available in one place is promising. Companies are building and experimenting with integrated platforms such as MITRE's Handshake and Deloitte's D Street. Experiences with an integrated system at Hewlett Packard are described in Brzozowski (2009) and Brzozowski et al. (2009). Commercial offerings are still taking shape, such as IBM Connections, a social networking capability that added blog, wiki, microblogging, forums, and communities over time, absorbing some of the functionality in research prototypes described earlier, and Sharepoint, Microsoft's document repository system that has also added blog, wiki, messaging, communities, and team sites.

Integrated internal systems have not yet fully proven themselves. The functionality is there, and organizations are trying them. The Holtzblatt et al. (2012) case study may be illustrative. After 2 years, 18% of employees reported benefits. This is significant, but short of the ultimate goal. Whether use will end up as widespread as e-mail is an empirical question.

45.4.4 Prospects for Enterprise Communication Technologies

In the consumer sphere, a decade of experimentation, exploration, and rapid change seems to have given way to a period of integration and consolidation. Organizations still face significant uncertainties, however. Should messaging remain a general platform or be embedded in different applications? Will an internal pedia or internal social networking platform be used, or should the focus be on making use of external tools? Can wiki and blog features address the chronic challenge of organizing information so that it can be retrieved with appropriate context? Other major challenges include addressing tensions

and opportunities around work–life balance for individuals and cross-enterprise communication with suppliers, customers, and partners.

Fears that accompanied the arrival of individual communication tools are dissipating. Trepidation is reduced as workers become more technology-savvy. They may as likely to see unmet potential as they are to imagine the worst.

People are using more tools and consequently value the capability to select among information threads rapidly and efficiently. The solution is not to merge all communication into a single channel; it is to provide a single place in which to quickly skim over or select among feeds, drawing on different channels for different purposes. Prospects for a new service improve if it appears alongside familiar services. The "place" can be a sequence of phone app buttons, a desktop window that aggregates multiple sources, or a large persistent display sitting to the side of one's primary work displays. At the same time, highly relevant information should also appear in context.

People report finding useful information and contacts within their organization through reading public blogs or Twitter streams issued by their organization. Is this evidence of the inadequacy of internal tools, a strength of external tools that should be exploited, or both? By analogy, if a vendor finds that people encountering a problem with their product use a search engine to find solutions on the web and do not go to the vendor's site for help, should the vendor double down on their help site, focus on improving the prospects for search engine users, or let the crowd handle it?

An organization could focus on improving internal tools or assist employees using external sites. Microsoft took the latter approach with externally facing blog servers and their new Social Connector, which enables access to Facebook, Twitter, and LinkedIn from within Office. This could impede a shift to internal tools—but for what organizations should or will such a shift take place?

Information threads—streams or rivers might be more apt metaphors—include not only communication with other people, but also meta-data and compilations of traffic from people, organizations, and objects, including video, sensor data, and other sources. No one has time to track everything in their work and personal lives that is potentially of interest. As the proportion represented digitally grows and the costs of displays, bandwidth, and computation drop, we can monitor more of it. Tools will enable faster access and better display, and new interaction models will enable us to scan information quickly and expand it as desired.

In this time of uncertainty and opportunity, enterprises that find solutions that fit their needs could do very well. The choices may be difficult. For example, tools for monitoring employee activity are improving rapidly. They could help but can create dilemmas for managers or IT staff who use them. Casual banter in a workplace probably increases social capital and strengthens ties in ways that enable employees to work more effectively; it probably builds skills and expands contacts that can later be drawn on for work purposes, but it also distracts people from their principal tasks. How much should managers support? Benefits are difficult to measure. Managers rarely have detailed enough knowledge of their subordinates' jobs to confidently draw lines, being too strict could be counterproductive if it drives employees to use personal devices to communicate during work hours.

Organizations that for legal or competitive reasons must restrict communication among employees or with the outside world face greater challenges as technology continues to dissolve boundaries. Any website open to posting creates a simple bridge between people who might otherwise have had great difficulty finding one another.

Another thorny issue is information preservation. It is cheap to record and archive just about everything. The cost of archiving video communication may currently be noticeable, but the trend is toward effectively free storage. Archiving has benefits—it is not always possible to know what will later be of use. Information can be mined to find ways to help people work more effectively. It also has risks—not only clutter and difficulty finding what *is* useful, but also in potential personal or organizational liability for what is said or done, especially when retrieved out of context. For example, excerpts from years of recorded conversations and meetings could be used to build a case for poor performance or for a hostile work environment.

Historically organizations have preserved essential information in structured documents vetted by managers. Most communication was ephemeral. Today much more is saved, and it could all be saved. Tools are available that automatically delete information on a set date; we can anticipate struggles over where to draw boundaries among individual workers, mangers, legal staff, and IT staff. The decisions may differ according to the nature of the activities involved—the legal restrictions, potential for liability, and evolving case law.

Despite these complexities, on balance, new communication and collaboration technologies represent astonishing tools for living and working more productively and pleasantly. It is tempting to imagine that it will be easy to get there. It will not be. The record of the past decade is that we are moving forward; new tools are being picked up, tried, and improved. Many are proving useful in workplaces. A learning curve is behind us; the benefits, along with new challenges, lie ahead.

Social Media Use within the Workplace

Ester S. Gonzalez
California State University at Fullerton

Hope Koch
Baylor University

46.1 Introduction

Social media (hereinafter SM) use within the workplace has increased 50% since 2008. Forrester Research predicts that the sales of software to run corporate social networks will grow 61% a year, becoming a $6.4 billion dollar business by 2016 (Mullaney 2012). This growth is fueled by practitioners who feel they "have to do something with social media" (Pettit 2010), but are unsure about SM's capabilities (Deans 2011). Scholarship in this area can provide practitioners guidance on how to deploy SM strategically.

The purpose of this chapter is to provide a starting point for scholarship on SM within the workplace by discussing the current state of research in this area. Workplace SM research deals with how organizations implement SM to manage their internal operations such as employee relationships, communication, knowledge management, and innovation. This differs from external SM implementations, which deal with organizations using SM to manage customers, suppliers, and business partners. Both are a part of Enterprise 2.0, a term coined by McAfee in 2006, to describe organizational implementations of Web 2.0 technologies (McAfee 2006).

The term, Web 2.0, first appeared in 2004. It refers to technological capabilities that enable users to easily create and exchange web-based content (Kaplan and Haenlein 2010). High-speed Internet, cloud computing, clients, servers, application programming interfaces, open source software development, and increasingly mobile applications provide the infrastructure supporting SM (Falls 2010). Web 2.0 is the platform that spurred SM's popularization. College students began using MySpace and Facebook in 2004, and as of March 2012, more than 900 million people actively use Facebook (Facebook 2012). In addition to social networking sites like Facebook and LinkedIn, SM applications include collaborative projects (e.g., Wikipedia), blogs (e.g., Twitter), content communities (e.g., YouTube), virtual game worlds (e.g., *World of Warcraft*), and virtual social worlds (e.g., *Second Life*) (Kaplan and Haenlein 2010).

Given that college students initially adopted SM for recreational purposes, the initial SM research (Boyd and Ellison 2007; Ellison et al. 2007; Valenzuela et al. 2009) investigated the characteristics of students most likely to use SM, how students use SM, and the benefits they garner from its use. Given SM's proliferation in people's personal lives and desires to attract millennial generation new hires who expect to use these technologies in their working environment (Koch et al. 2012a; Majchrzak et al. 2009; Smith 2011), businesses began experimenting with SM in 2006.

The majority of research focuses on *external* SM use, describing how organizations like Wal-Mart, Dell, Starbucks, Ford, Burger King, and Zappos use online forums like Twitter, Facebook, blogs, and company-hosted forums (Culnan et al. 2010; Di Gangi et al. 2010). Primary SM uses include marketing, branding, customer service, and recruiting (Culnan et al. 2010; Gallaugher and Ransbotham 2010).

External SM research identified two key issues facing organizations: managing customer dialog and managing online communities. SM changes how organizations advertise their products from the historical megaphone strategy where companies broadcast what they want customers to know to strategies that incorporate customer-to-company and customer-to-customer communication (Gallaugher and Ransbotham 2010). Online community research identified four issues facing businesses: understanding the ideas posted in online communities, choosing the best ideas, balancing openness with competitiveness, and sustaining the community (Di Gangi et al. 2010).

Research on SM use *within the workplace* is more sparse but needed (Huysman 2011). Whereas workplace SM implementations were mostly experimental until 2011 (Rozwell 2011), in 2012, organizations began embracing SM applications to try and connect employees and increase their satisfaction and commitment despite geographic dispersion (Mullaney 2012). Organizations like Best Buy, IBM, and Kaiser Permanente are replacing their intranets with workplace SM sites (Bennett 2009). The most common software used to build these sites is Microsoft SharePoint. In fact, a survey of 1400 small, medium, and large organizations worldwide indicated that 70% of medium and large organizations build their workplace SM sites with Microsoft SharePoint (Ward 2012), which they customize to meet organizational needs (Koplowitz et al. 2011).

46.2 Underlying Principles

SM use within the workplace is based on three underlying principles: contribution, communication and collaboration, and social–work life integration. Table 46.1 highlights the theories that have guided research in this area.

TABLE 46.1 Theories Guiding Research on Social Media Use within the Workplace

Theory	Use in SM Workplace Research
Boundary theory (Ashforth et al. 2000; Sundaramurthy and Kreiner 2008)	Used to investigate SM's role integrating social life into the workplace (Koch et al. 2012a)
Social capital theory (Coleman 1988)	Used to investigate how workplace SM can help employees build capital to improve their working relationships (DiMicco et al. 2008)
Structural holes theory (Burt 1992; Granovetter 1973)	Used to investigate how SM promotes innovation and relationships by bringing together weak ties (Gray et al. 2011)
Theory of IT-culture conflict (Leidner and Kayworth 2006)	Used to investigate how organizations can resolve the conflict associated with implementing SM in the workplace (Koch et al. 2013)
Theory of positive emotions (Fredrickson 2000; Fredrickson and Branigan 2005)	Used to investigate why new hires used workplace SM and the benefits the SM initiative provided the new hires (Koch et al. 2012a; Leidner et al. 2010)

46.2.1 Contribution

Workplace SM value depends on employees frequently contributing small pieces of valuable knowledge that are easy to acquire, share, and use (Yates and Paquette 2011). A common misconception is that the crowd-sourcing capabilities of workplace SM will draw employees to adopt SM tools (Bradley and McDonald 2011). Unfortunately, organizations often struggle with employee adoption (Jackson et al. 2007; Koch et al. 2013). These struggles spawn from an interrelationship between the technology and the employees' workload. Some employees feel SM is a waste of time or that they are too busy to contribute, while others may not fully understand how their SM use may benefit the organization (Kiron 2012a; Koch et al. 2013). Many employees believe that if their coworkers see them contribute, they will think that they do not have enough work to do—a negative stigma (Koch et al. 2011).

To encourage employee participation in workplace SM, organizations have provided effort-investment and financial and reputational incentives. Effort-investment incentives allow employees to contribute to the SM with no extra effort. For example, corporate bookmarking applications allow employees to share the resources they consider valuable with coworkers simply by bookmarking resources in their own browser. Financial incentives include funding to develop popular ideas submitted over the SM, giving monetary awards to people and teams with the best ideas as well as incorporating workplace SM participation into performance reviews. For instance, Threadless t-shirt design system pays royalties to employees whose ideas are put into production (Malone et al. 2010). Reputational incentives include peer recognition, management recognition, and leadership opportunities. Tata consultants' leader board tracks the most prolific and highest-rated discussion board contributors (Kiron 2012c). Peer recognition and being on top of the leader board have led employees to respond to questions outside of their work group and helped Tata identify skills they did not know these employees possessed.

Even though organizations have adopted strategies to encourage employee contributions, the SM initiative's purpose and the organization's culture affect the success of workplace SM initiatives. Clearly, showing the purpose of the workplace SM by linking it to solving employee problems (Bradley and McDonald 2011) and monitoring outcomes rather than behaviors facilitate workplace SM success (Majchrzak et al. 2009). In addition, cultures characterized by youth, technical prowess, and enlightened leadership tend to successfully utilize workplace SM (Kiron 2012c). Employees want to understand why they should use the SM and feel confident that top management supports their SM use.

46.2.2 Communication and Collaboration

Both employees and managers adopt SM because SM encourages open communication and collaboration by providing forums where all employees can reach across time, space, interest, function, and hierarchy to seek and contribute information throughout the organization (Majchrzak et al. 2009). Using SM tools (e.g., wikis, blogs, and discussion boards), employees can see, use, reuse, augment, validate, critique, and rate one another's ideas (Bradley and McDonald 2011). This type of information sharing encourages transparency, informality, and democracy.

46.2.2.1 Employee Empowerment

SM's communication and collaboration principles have freed and empowered employees. Instead of responding to the same question repeatedly using private channels such as e-mail or phone calls, SM allows knowledge workers to publicly respond to questions (McAfee 2009). For example, a Kaiser Permanente team leader capitalized on SM's collaborative capabilities by posting employees' public relations plans on its SM site. This enabled all team members to comment on the proposals, without losing information in e-mails or offline conversations and documents (Kiron 2012b).

Empowered employees use SM to promote projects, advance their careers, and offer insight. Employees promote projects by driving traffic to project web pages and collecting comments that both shape the project and document support (DiMicco et al. 2008a,b; Majchrzak et al. 2009). SM supports

career advancement by allowing employees to highlight their skills and interests to management and coworkers (DiMicco et al. 2008; Koch et al. 2012a). The openness embedded in SM applications allows employees to offer insights to problems outside their job responsibilities. USAA's new hires use the SM site to volunteer for projects that demonstrate their web development, graphic development, and project management skills to management (Leidner et al. 2010).

Management generally implements workplace SM to help employees address organizational problems including knowledge preservation, solution generation, and strategic insight. For example, IBM's Innovation Jam brings employees, clients, and partners together to discuss new business opportunities, whereas Scotland's Royal Bank uses a virtual world to gather employees' feedback on new banking environments (Birkinshaw et al. 2011).

46.2.2.2 Loss of Managerial Control

Given that SM promotes open communication, at times, employees may use SM to address problems that management would prefer employees ignore. In a notable example (da Cunha and Orlikowski 2008), petroleum company employees used an online discussion board to cope with organizational changes that were threatening their identity and livelihood. In SM postings, employees vented their anger and increased their solidarity by sharing painful and humiliating experiences. Their postings portrayed management as incompetent, insensitive, and unskilled while employees were portrayed as committed, competent, and willing to change. In another example, Telco's employees "hid behind the technology" to anonymously air grievances that they would not discuss when people knew their identity (Denyer et al. 2011).

As such, it is no wonder that management is still grappling with SM's empowerment capabilities. Organizational crowd-sourcing innovations often threaten innovation managers who feel a loss of control and protest about "having to spend their time sorting through the junk employees submit" (Kiron 2012c, p. 3). Middle managers have the most difficulty accepting workplace SM, possibly because SM threatens their role conveying information up and down the hierarchy (Kiron 2012c; Koch et al. 2012a; Leidner et al. 2010).

Many organizations have implemented workplace SM guidelines to address organizational fears about SM and help employees understand organizational-appropriate SM use (Bradley and McDonald 2011). These guidelines indicate what users can and cannot do with SM (Kaganer and Vaast 2010). However, most of the guidelines reflect a lack of understanding of SM's potential and instead see it as a risk or a way to convey management's message. The organizational policies address the risks by telling employees to consult authority if they are uncertain and that improper SM use could result in disciplinary actions. In more than one case (da Cunha and Orlikowski 2008; Denyer et al. 2011; Kiron 2012c), management has controlled information flow by disabling employees' ability to comment and instead appropriating SM as a megaphone to inform employees about policies and procedures.

46.2.3 Social and Work Life Integration

In addition to loss of managerial control, some organizations are concerned about the social aspect of workplace SM. In fact, organizations that implement workplace SM to encourage employees to make and maintain friends at work simultaneously struggle with whether the benefits of socializing outweigh potential productivity losses (Koch et al. 2012a).

Researchers have used boundary theory and the theory of positive emotions to investigate the SM principle of social and work life integration. Boundary theory (Ashforth et al. 2000) explains how people assume various roles (e.g., friend, coworker, supervisor, and family) that are determined by their task and social system (Katz and Kahn 1978; Perrone et al. 2003). When competing roles (e.g., supervisor and friend) interrupt each other, conflict occurs.

Contrary to boundary theory, an investigation of workplace SM use found that blurred work-social boundaries can create positive emotions (e.g., joy, contentment, and happiness) (Koch et al. 2012a)

for SM users. This research combined boundary theory with the broaden and build theory of positive emotions. The broaden and build theory of positive emotions posits that positive emotional experiences can broaden an individual's thought–action repertoire, which can then lead to personal resource development. Personal resources include physical, social, intellectual, and psychological resources that individuals can draw upon when faced with negative situations (Fredrickson 2004).

Workplace SM use can increase employees' attachment to the workplace and improve working relationships by providing a forum for employees to make and maintain friends in the workplace (DiMicco et al. 2008; Koch et al. 2012a). Several SM applications support social–work life integration including employee profiles, activity feeds, and event planning (Koch et al. 2012a). Employee profiles encourage employees to share aspects of their personal lives including pictures and hobbies. Employees frequently scan coworker profiles to find a common ground with people they are seeking expertise from. Activity feeds allow employees to stay in touch with other employees whom they have met. Event planning features facilitate in-person social events where employees can meet one another and build relationships. Employees use these applications primarily to build stronger relationships with their acquaintances (i.e., weak ties) rather than reach out to people that they know well (DiMicco et al. 2009).

This relationship building helps build *social capital* (Coleman 1988) through trust, reciprocity, identification, and shared language (Tan et al. 2009). Social capital is difficult to see and may involve establishing purposeful relationships to generate benefits and offering short- and long-term kindness with the assumption that people will return this kindness (Coleman 1988; Nahapiet and Ghoshal 1998).

Combined SM applications engender bridging, bonding, and maintained social capital (Ellison et al. 2007). Bridging social capital involves weak ties between individuals who may provide useful information and new perspectives (Granovetter 1973). Bonding social capital is found in tightly knit emotionally close relationships such as family and close friends. It gives employees people to turn to in times of need. Employees experience maintained social capital when they can rely on their coworkers to do small favors (Ellison et al. 2007).

46.3 Impact on Practice

Most managers who champion workplace SM believe that better communication characterized by personal relationships, openness, and collaboration leads to positive outcomes for employees that transfer to the organization. Employees who use workplace SM may experience intrinsic motivations like job satisfaction, freedom, and fun (Tan et al. 2009) and engage in corporate citizenship behaviors (DiMicco et al. 2008, 2009; Skeels and Grudin 2009). This section highlights common SM applications and workplace SM initiatives that have proven effective.

46.3.1 Applications

Most workplace SM implementations encompass a common set of applications, which organizations integrate into customized portals. Table 46.2 describes these applications that have six characteristics (McAfee 2009): search, links, authoring, tags, extensions, and signals. Workplace SM applications may make searching and finding information more successful by allowing employees to share and post information in ways that they consider most beneficial (Kiron 2012c). Links may break down existing hierarchical data structures that have historically defined who can discuss certain topics as well as generate, share, and access information (Kiron 2012c). Links enable employees to define how the organization will organize its documents by promoting a self-imposed structure, which emerges out of everyday work practices. Authoring shifts corporate intranets from a top–down information flow reflecting management's voice to a tool that empowers employees to update information and provide commentary. Tags allow employees to keep up with useful web resources. Employees can assign descriptive reminders to the content they have accessed and browse their coworkers' content. Signals notify employees when new and relevant information is added such as when coworkers update documents of interest.

TABLE 46.2 Social Media Applications

Feature	Description
Blogs	Allows employees to author individually by posting thoughts and ideas in reverse, chronological order
Business intelligence	Analyzes e-mails, instant messaging, and virtual space usage to identify social networks and value-added networks
Collaborative projects	Enables employees to simultaneously create content
Content communities	Enables employees to share text, videos, photos, and PowerPoint presentations
Discussion boards	Forum for asking questions and leaving responses
Social bookmarks and tagging	Allows employees to bookmark and categorize frequently accessed documents and sites to share with colleagues
Social networking sites	Enables employees to construct a digital identity by developing a profile, articulating a list of users with whom they share a connection, viewing their list of connections, and viewing connections made by others within the system (Boyd and Ellison 2007). This is similar to public sites like Facebook and LinkedIn
Virtual worlds	Allows employees to replicate a three-dimensional environment that simulates real life
Wikis	Allows groups of employees to create and edit websites that are shared throughout the organization

46.3.2 Outcomes

While the business press is filled with stories of how workplace SM benefits organizations (Bradley and McDonald 2011; Li 2010; McAfee 2009), academic research highlights four areas where organizations have effectively deployed workplace SM. These include acclimating new employees, changing organizational culture, managing knowledge, and promoting innovation.

46.3.2.1 Acclimating New Hires

Organizations have leveraged workplace SM to acclimate new hires into the workplace (Koch et al. 2012a; Leidner et al. 2010). USAA implemented its workplace SM in 2009 in efforts to attract and retain college hires in the IT area. USAA's new hires use workplace SM throughout their new hire program. In the early stages of their program, these tools help new hires become familiar with their area, learn where to go for help, find people like them, make friends, and learn about social events. In the later stages of their program, the workplace SM allows more senior new hires to develop leadership skills by mentoring first-year new hires, developing content, and leading events.

While managers recognize several benefits from integrating SM into new hire acclimation programs including better retention, recruiting, morale, engagement, and productivity, concerns are still prevalent (Koch et al. 2012a). Since workplace SM shifts some of the burden of mentoring new hires away from middle managers while simultaneously exposing the new hires to upper management, middle managers can experience isolation and inequity. These emotions often manifest themselves in middle managers protesting that the SM encourages the new hires to socialize during the workday.

46.3.2.2 Changing Organizational Culture

In addition to making the workplace more social, organizations have implemented SM to also bring about information sharing cultural changes (Koch et al. 2012a; Majchrzak et al. 2009). SM promotes information sharing cultures in several ways. User profiles let employees know their coworkers' current projects and expertise. Document repositories provide central locations where employees can access

documents such as contracts. Wikis and blogs allow employees to share meeting notes and frequently asked questions. Activity feeds keep project team members up to date on one another's project status. Organizations have leveraged these applications to promote employee health and safety and share best practices (Bradley and McDonald 2011).

SM can make the workplace more social by promoting social events where employees can physically get together and providing online forums for employees to learn about one another and nurture their personal relationships. These activities encourage employees to share their personal interests and hobbies. As part of its cultural change effort, a security company hosted a luncheon where employees brought and discussed pictures of themselves having fun (Koch et al. 2013). Subsequently, management encouraged the employees to post their pictures along with their hobbies on the workplace SM site.

Despite SM's potential to promote cultural changes, employees and management often challenge these efforts (Denyer et al. 2011; Koch et al. 2013). Both groups are concerned about socializing at work (Skeels and Grudin 2009), unnecessary distractions (O'Driscoll and Cummings 2009), and protecting confidential information from unauthorized employee access. While employees are sometimes reluctant to communicate openly in fear of management ramifications (Hewitt and Forte 2006; Skeels and Grudin 2009), management wants to control communication. SM can facilitate cultural change, when management highlights the need for organizational change and implements leadership-based, policy-based, and socialization-based integration mechanisms to align the SM with the organization's culture (Koch et al. 2013).

While SM-induced organizational change research is emerging, the theory of IT-culture conflict has proven useful in this area (Koch et al. 2013). This theory posits that IT implementations may encounter system conflict when the values embedded in the IT conflict with group member values (Leidner and Kayworth 2006). The theory suggests that organizations can resolve IT-culture system conflict by implementing integration mechanisms that bring group member values and the IT values closer together.

46.3.2.3 Managing Knowledge

Organizations can use SM to manage knowledge by facilitating knowledge sharing, knowledge transfer, and knowledge preservation (Bradley and McDonald 2011; McAfee 2006, 2009). In contrast to the knowledge management systems of the 1990s that required employees to preserve their knowledge by entering best practices and experiences in knowledge repositories, workplace SM can capture employee's knowledge as part of their routine work practices (McAfee 2006).

Workplace SM facilitates knowledge sharing by allowing employees to pose and answer questions. Employees who respond to the forums are often people with interest in an area rather than people assigned to an area, thus allowing organizations to tap into hidden skill resources. SM enables employees to find knowledge resources within the organization. For example, employees located at different worldwide divisions can locate their counterparts at other divisions. SM's social aspect (i.e., the profiles and the activity feeds) helps promote relationships that may ensure that the counterpart responds to the request for help.

SM facilitates knowledge transfer by allowing coworkers to stay abreast of one another's activities and facilitating succession. As an example of staying abreast of coworker activities, employees in the defense industry, who had historically e-mailed their managers weekly activity reports, began using SM to post their activity reports (Koch et al. 2013). This allowed their team members to monitor their project progress (Koch et al. 2013). By giving new team members access to their predecessor's portal, SM enables new employees to learn who their predecessor communicated with and the electronic resources they used.

Employees can use SM's knowledge transfer capabilities to gain broad-based or pulse knowledge (Jackson et al. 2007). Broad-based knowledge may include strategies, initiatives, policies, or events. For example, reading coworkers' blogs can help employees understand how changes to the companies' pension program affect them (Jackson et al. 2007). Pulse knowledge gives employees an insight

to their coworkers' thoughts. Pulse knowledge can help executives assess organizational climate, assist human resources professionals to create a positive working environment, and allow newcomers to fit in.

46.3.2.4 Promoting Innovation

Research on workplace SM-enabled innovation includes business success stories, explanations of how organizations have used SM to promote innovation, and the relationship between SM tools and innovation. Business press authors like Charlene Li (2010), Andrew McAfee (Kiron 2012c; McAfee 2009), and Gartner Group executives (Bradley and McDonald 2011) share many case studies of organizations that have leveraged workplace SM to promote innovation. These case studies suggest that SM-enabled innovations have positively impacted efficiency, quality, culture, savings, and revenue. Examples range from a semiconductor design company that increased its engineering productivity by 25% to a healthcare company that created a collaborative community to provide better care for the elderly (Bradley and McDonald 2011).

With innovation becoming the entire organization's responsibility (Birkinshaw et al. 2011), workplace SM, like event planning systems, internal rating systems, and innovation forums, has the potential to involve all employees in the innovation process. Event planning systems promote innovation contests. USAA held a contest that encouraged its employees to develop a banking application for the Android mobile phone operating system before Android became mainstream. Innovation forums and internal rating systems allow employees to post, develop, and vote on innovative ideas. Threadless (Malone et al. 2010), IBM, and Scotland's Royal Bank (Birkinshaw et al. 2011) have leveraged ideas generated from workplace SM by creating connectors between idea generators and those that can make the idea come to life (Whelan et al. 2011).

Both blogging and social bookmarking can foster innovation by bringing together weak ties. Explicated in structural holes theory (Burt 1992; Granovetter 1973), weak ties describe people who are acquaintances and as a result of operating in different networks possess different information. Structural holes theory predicts that bridging gaps between unconnected individuals can expand one's sphere of influence, build knowledge resources, and foster innovation.

As an informal mechanism for linking weak ties, blogging has the potential to link disparate parts of the organization in an initial step toward promoting innovation through cross-functional collaboration (Jackson et al. 2007). As an example, a cement building and materials company credited its SM-enabled cross-functional collaboration with facilitating corporate process changes that helped decrease its emissions by raising its alternative fuel use (Bradley and McDonald 2011).

At the individual level, organizational social bookmarking applications can increase employee innovativeness when the process of reading coworkers' bookmarks provides employees novel information (Gray et al. 2011). For example, one employee attributed regularly reading his coworkers' bookmarks to staying abreast of developments in the visualization area and developing creative ideas for clients (Gray et al. 2011).

46.4 Future Research

Given the nascent stage of SM use within the workplace, additional research is necessary to better understand the phenomenon at both organizational and individual levels.

46.4.1 Organizational Level

Fruitful organizational level research topics include SM's impact, governance, and sustenance. Since SM often comes in a suite with a variety of applications including blogs and wikis, we need to understand the workplace impact of both particular SM applications (e.g., social networking and wikis) and SM initiatives as a whole.

Currently, practitioners have little guidance on what to do with SM or which SM applications may help solve workplace problems (Pettit 2010). To help practitioners, researchers should continue to investigate SM applications in the workplace, as part of a larger effort to build a workplace SM application taxonomy. Such a taxonomy would help practitioners understand which SM applications are best suited to address workplace needs like creating knowledge, fostering commitment, and promoting change. Further taxonomy development might investigate employee types that are most likely to benefit from particular SM applications. This research could investigate SM in different functional areas (e.g., accounting, marketing, information technology), levels (e.g., executive, middle management, entry level), and maybe even industries (e.g., retail, energy, distribution).

In addition to understanding how SM applications like wikis and social networking affect various processes in the organization, we need to understand how SM as a whole impacts the organization. This stream of research might bolster the case studies linking workplace SM use to positive organizational outcomes with quantitative evidence (Gray et al. 2011; Kiron 2012a). Research might measure how workplace SM initiatives affect collaboration, learning, information sharing, knowledge management and communication, and the resulting impact this has on key performance indicators such as turnover, innovation, and return on investment.

We also need to understand the dark side of SM in the workplace. While both the trade press (Cain et al. 2011) and academic articles (Denyer et al. 2011; Koch et al. 2013) document management's and employees' concerns about SM reducing productivity, we need quantifiable evidence about SM's negative effects in the workplace. Research in this area might investigate lost productivity, workplace disruption, and information overload.

These potential negative ramifications of workplace SM use might be addressed with SM governance. Governance refers to the management, policies, guidance, processes, information rights, and decision rights associated with an organization's SM initiatives (Weill and Ross 2004). Since many organizations implemented SM in an effort to experiment with this new medium and its open, collaborative, nonhierarchical values (Koch et al. 2013), we need to know more about effective SM governance. Research in this area might describe both effective and ineffective SM governance practices that address content management, information credibility, and employee rights. How do organizations balance the need for confidentiality vs. the need to share information, workplace surveillance vs. employee privacy, and encouraging collaboration vs. stifling gossip?

In addition, we know little about sustaining SM initiatives. Future research needs to address this along with how to integrate SM into existing work practices. As SM technologies continue to advance and incorporate Web 3.0, big data, predictive analytics, and mobile computing (Andriole 2010; King 2012), research might investigate mindful SM adoption (Swanson and Ramiller 2004).

46.4.2 Individual Level

Individual-level research will help us understand how workplace SM initiatives affect employees. How does SM impact communication processes like attention, persuasion, learning, and leadership? How does SM change coworker relationships? Some research areas include the effect of online relationships on offline relationships, social isolation, and weisure time. Weisure time refers to a time where employees cannot distinguish between where work ends and their social life begins (Luttenegger 2010). While we know something about how weisure time impacts employees from an organizational perspective (Koch et al. 2012a), we know less about the impact on the employees' personal life.

46.5 Conclusion

This chapter has provided a starting point for scholars interested in understanding SM use in the workplace. Contrary to SM use in the public domain (e.g., Facebook and LinkedIn) and organizational SM use for external relationship (e.g., customers and business partners), workplace SM use deals with

employees. While these initiatives can empower employees, they can also result in loss of managerial control and social–work life integration. Case studies describing workplace SM uses such as acclimating new hires, changing organizational culture, managing knowledge, and promoting innovation characterize research in this area. Future research needs to investigate the quantifiable impacts of SM as well as its governance and sustenance. Some theories that may be useful to guide these inquiries are available on the IS theories page at http://istheory.byu.edu/wiki/Main_Page.

All problems in computer science can be solved by another level of indirection.

David Wheeler

47.1 Overview of Virtualization

47.1.1 What Is Virtualization?

Virtualization is the abstraction of physical components, such as CPU, memory, and storage, into logical management entities. In other words, virtualization provides an additional layer of *indirection* that separates the actual resource pool from the management function, in order to achieve better system utilization with improved manageability (Figure 47.1). As an example, modern computer architecture requires a memory component to facilitate fast data access between CPU and storage devices. While outperforming hard disk drives (HDDs) in regard to the latency of data read/write, memory is usually much smaller in capacity than HDD and cannot satisfy the memory allocation requests from applications all the time. With the aid of virtualization, the host operating system (OS) can create a *virtual memory*, which essentially resides in the HDD, and allocate the virtual memory space for application memory requests if the physical memory is saturated. From the application perspective, the virtual memory appears the same as the physical memory, and each Input/Output (I/O) request will trigger a mapping, performed by the OS, from the virtual memory space to the actual location on the HDD. The complexity of indirection is transparent to the application and hence improved management flexibility and efficient system utilization can be achieved in a nonintrusive fashion. The concept of "additional layer of indirection" characterizes the

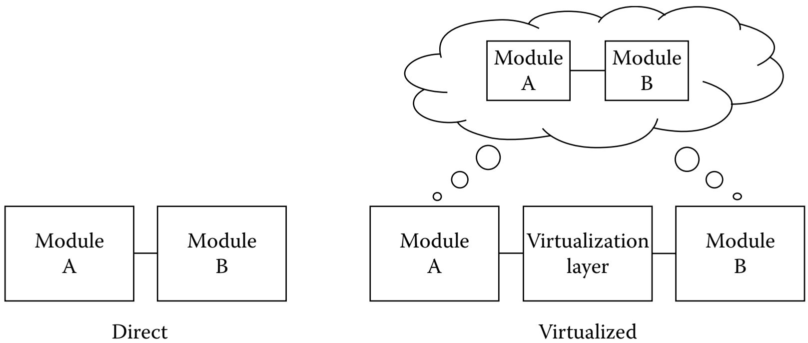

FIGURE 47.1 Virtualization as an additional layer of indirection.

essence of virtualization techniques that have been widely applied in many information technology (IT) applications, ranging from the inception of virtualization on IBM mainframes in the 1960s to the recent revitalization in emerging cloud computing paradigm shift.

47.1.2 Why Virtualization?

The key advantage of virtualization lies in the improved resource utilization and enhanced management flexibility. The virtualization layer presents a consistent interface to the system administrator while hiding the details of the underlying physical resources. The system administrator will have a logical view of the resource pool, and favorable features such as efficient resource allocation and dynamic control can be achieved. For example, a *virtual machine* (VM) can be created, which is a virtualized server with an isolated and complete OS (possibly different than the OS of the physical host server) and behaves exactly like a physical machine. Furthermore, multiple VMs can be consolidated into a single physical host machine to simplify the management overhead and reduce the operation cost such as electricity bills for cooling. By virtualizing all physical resources into a unified logical resource view, the overall IT infrastructure and system resources can be managed and shared more dynamically. For example, the disk space of one physical host can be shifted to another host that is running out of storage capacity, without interrupting the ongoing applications. Additional hardware such as HDD can be easily added to the system while keeping the logical resource view intact. Therefore, the overall IT infrastructure is more responsive and agile to the real-time environment changes, which facilitates better and faster business decisions. Also virtualization naturally supports multi-tenant IT infrastructure by virtualizing a separate environment for each tenant, and the overall system resources can be shared in an integrated fashion, where new value-added services can be deployed and delivered with less cost and complexity.

47.1.3 Types of Virtualization

In essence, virtualization provides a logical abstraction of the physical resources in a variety of forms such as host machine hardware, networking resources, and storage capacity, among many others. Next, we will introduce three common types of virtualization, i.e., platform virtualization, storage virtualization, and network virtualization, which are widely deployed in many IT scenarios such as cloud computing infrastructures.

47.1.3.1 Platform Virtualization

Traditional computers use specific hardware architectures with a host OS that is compatible with the underlying hardware platform. Therefore, the OS and the host hardware platform need to be developed side by side in order to interact properly. With platform virtualization, or sometimes referred to as

hardware virtualization, multiple guest OSs (independent of the host OS) can run on the same physical host machine simultaneously and share the hardware in a coordinated fashion. The key enabling technique is a software, namely, *hypervisor*, which runs on the physical host and provides an integrated interface between the hardware platform and the guest OSs. Popular hypervisors include KVM [11], Xen [20], VMware ESX [18], Microsoft Hyper-V [12], and IBM PowerVM [7], among many others. By utilizing hypervisor and platform virtualization, multiple VMs are created on a physical server with their own set of virtual hardware. The interactions of VMs and the underlying host machine are intercepted and translated by the hypervisor. For example, a hypervisor can intercept the instructions of the guest OS of one VM and translate them to the native instruction set of the host machine. This enjoys great practical merit for enterprise IT administrators that need to execute legacy machine code on newly developed hardware platforms. In addition, the hypervisor can monitor the status of each VM, such as I/O rate and memory usage, and allocate the hardware resources on the host platform appropriately, in order to prioritize workloads and/or to achieve better system utilization. Therefore, hypervisors are also referred to as *virtual machine managers* (VMM). Due to its popularity, hypervisor architecture design and optimization have been studied extensively in the literature. For example, Barham et al. [23] and Menon et al. [32] discuss the overall architecture design of Xen and several performance enhancements to its I/O channel, respectively. In [24], a novel architecture of virtualization is designed and analyzed that enables a nested virtualization environment, i.e., a hypervisor can host other hypervisors with their own VMs, on existing x86-based systems. For more discussions on x86 virtualization, refer to [21].

According to the methods of interaction with host hardware platform, hypervisor can be categorized into two major classes, i.e., *bare metal* hypervisors and *hosted* hypervisors, as shown in Figure 47.2. Bare metal hypervisors interact with the physical hardware directly, e.g., KVM and ESX, while hosted hypervisors reside in a host OS, e.g., Oracle VM VirtualBox [15] installed on a Windows machine. Hypervisors usually can support virtualization in one of two modes, i.e., *full virtualization* and *paravirtualization*. In full virtualization mode, hypervisors provide a complete simulation of the underlying hardware to unmodified guest OSs. While in paravirtualization, hypervisors run modified guest OSs that leverage an Application Programming Interface (API) similar to that provided by the underlying hardware. Therefore, hypervisors with paravirtualization capabilities are less complex and provide faster interactions with the VMs due to reduced hardware and firmware emulation as well as less layers of indirection, as illustrated in Figure 47.3.

Platform virtualization provides significantly improved management flexibility compared to traditional IT architectures. For example, existing virtualization management tools, such as VMware's vMotion [19], are able to nondisruptively migrate a VM across multiple physical servers. VM migration facilitates improved server load-balancing, higher availability (e.g., moving VMs away from a failing or overloaded server), and easier management (e.g., moving VMs away from an old server scheduled for replacement). At the start of a migration, a copy of the VM, which resides in shared storage, is placed on the target server. Next, the active memory and execution state from the source server is transferred to the target until the physical location of the VM is updated.

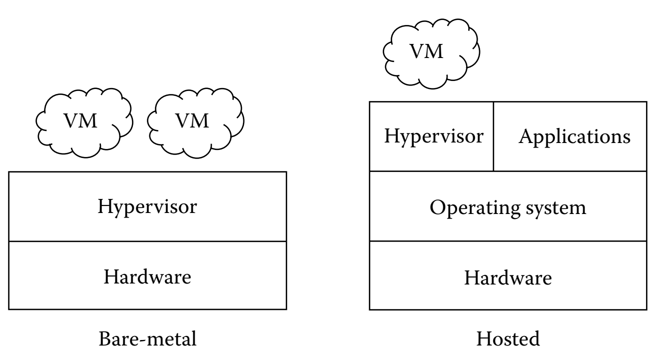

FIGURE 47.2 Bare metal hypervisors and hosted hypervisors.

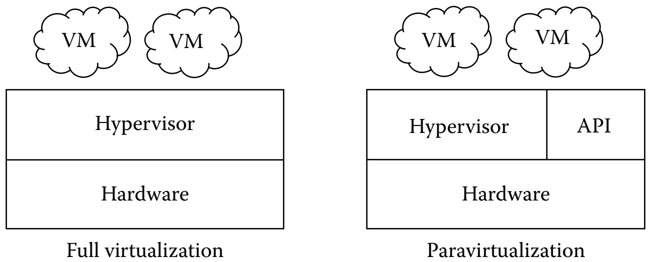

FIGURE 47.3 Full virtualization and paravirtualization.

47.1.3.2 Storage Virtualization

Storage virtualization is the abstraction and aggregation of physical storage capacity from multiple devices for efficient allocation and management in a coordinated way. By using storage virtualization, the complexity of physical storage devices is hidden from the management viewpoint, which is crucial for reducing the difficulty of management and improving performance. In the next section, we will elaborate on various techniques used in existing storage virtualization systems and the benefits of storage virtualization.

47.1.3.3 Network Virtualization

Network virtualization is the abstraction of network resources, such as routers and switches, as well as the physical network link bandwidth, into a logical *slice* of resources. With network virtualization, a single physical network appears to be multiple heterogeneous network architectures, and the overall network is shared among them. Similar to platform virtualization, network virtualization provides improved flexibility and enhanced network manageability. Each virtual network consists of a collection of virtual nodes and virtual links, and two virtual nodes can be connected via a virtual link regardless of their physical locations. In other words, network virtualization provides a shared yet isolated network environment that allows the coexistence of multiple overlay networks. Therefore, it is of particular interest to networking researchers since this enables deployment of heterogeneous network architectures and protocols on a shared physical infrastructure, where new networking techniques can be tested and evaluated. In [28], a systematic virtual network design that separates the network infrastructure provider and the network service providers is proposed. Such an architecture allows the traditional Internet Service Provider (ISP) to provide value-added services with customizable network protocol stacks. Bhatia et al. [25] propose a platform for virtualized networks based on commodity devices. Another example is the U.S. National Science Foundation's (NSF) support of the Global Environment for Network Innovations (GENI) project [17], which utilizes network virtualization techniques to provide a large-scale shared virtual test bed for networking research communities.

Traditional network virtualization techniques include virtual local area networks (VLANs) and virtual private networks (VPNs). In VLAN, a logical network is formed by a group of nodes with the same VLAN ID. The switches that support VLAN will distinguish packets (frames) with different VLAN IDs and forward them as if they belong to different separate LANs, which is a desired feature for multiple organizations with the same shared network structure and traffic separation requirements, possibly due to privacy and security reasons. In contrast, VPN is a virtual private network connecting multiple sites of the same organization using secured tunneling techniques, e.g., generic routing encapsulation (GRE) [9] and IPsec [10].

The recent revitalization of network virtualization is largely due to the active research activities on *software defined networking* (SDN) techniques [36]. As a viable means of achieving the general concept of "programmable networks," SDN allows the system administrator to define the network rules and shape the traffic in a way that is more flexible than the existing solutions can provide. For example, Open vSwitch [13] is an open source software stack that can virtualize a host as a programmable switch

and enforce customized forwarding policies according to each packet's characteristics, e.g., source and destination address. Moreover, Open vSwitch supports OpenFlow [14], which is a communication protocol to allow switches to obtain control information, i.e., forwarding rules, from a central repository, in order to separate the data plane and control plane for efficient and programmable network utilization. As an example, in the emerging techniques of converging LAN/SAN (storage area networks), Ethernet is used to carry both regular data traffic and storage traffic, which was supported by Fibre Channel in traditional SANs, via either Fibre Channel over Ethernet (FCoE) or Internet Small Computer System Interface (iSCSI) protocols. In order to support lossless transmission for storage traffic, the system administrator can assign higher priorities for FCoE and iSCSI packets at the Ethernet switch, compared to regular data packets, to avoid packet losses due to network congestions. Such network-wide prioritizing policies can be configured conveniently via the OpenFlow protocol, with the aid of the centralized repository, without manual configurations on each router.

47.2 Storage Virtualization Explained

The Storage Networking Industry Association (SNIA) defines storage virtualization as follows [16]:

1. The act of abstracting, hiding, or isolating the internal functions of a storage (sub)system or service from applications, host computers, or general network resources, for the purpose of enabling application and network-independent management of storage or data.
2. The application of virtualization to storage services or devices for the purpose of aggregating functions or devices, hiding complexity, or adding new capabilities to lower-level storage resources.

The general structure of a storage system consists of host servers (usually the initiators of data read/write operations), disk subsystems (physical location of stored data), and the network connecting them, for example, SAN fabric based on Fibre Channel, or Ethernet IP networks. Storage virtualization can be implemented at many places along the I/O path, as illustrated in Figure 47.4, which should be determined according to the IT requirements and business needs. Next, we will introduce three common places where storage virtualization is implemented, i.e., server, disk subsystem, and SAN storage virtualization. It is worth noting that in practice, a combination of storage virtualization at different levels can be utilized according to specific IT requirements such as fault tolerance, scalability, ease of management, etc.

47.2.1 Server Storage Virtualization

As one of the earliest forms of storage virtualization, the server's OS utilizes a logical abstraction of storage capacity, in tandem with the file system, to manage the mapping between data and actual location on the disk. For example, a physical hard disk can be divided into multiple *partitions* to isolate the disk space into multiple parts. The system administrator may create a partition for Windows OS and another partition for Linux to prevent overlapping of different file systems and conflicts. A partition can consist of multiple disk *blocks*, where each block is the smallest operation unit between the OS and the

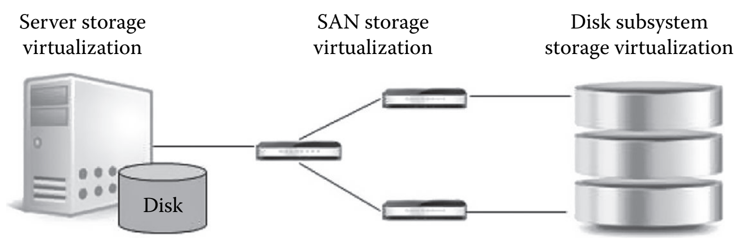

FIGURE 47.4 Storage virtualization on the I/O path.

hard disk. By virtualization, the system administrator can create a *logical* space on the disk, namely, a *volume*. Instead of physical partitions, the OS uses logical volumes to allocate storage spaces. In many modern OSs, such as Linux, there is a separate module, referred as the logical volume manager (LVM), to manage the mapping between physical disk blocks and logical blocks that can further aggregate to logical volumes. The LVM can resize each logical volume on the fly according to current system utilization and application demands. It is also common that multiple physical blocks are mapped to the same logical block for reliability concerns, e.g., mirroring.

47.2.2 Disk Subsystem Storage Virtualization

A disk subsystem is a specialized storage device optimized for fast I/O access, improved storage capacity utilization, and high availability, e.g., IBM System Storage DS8000 Series products [8] and EMC VMAX Family [5]. Physical disks are grouped together and presented as a logical disk using a storage virtualization technology known as redundant array of independent disks (RAIDs). Depending on its level, RAID provides striping for performance, mirroring for reliability, hot spares for resiliency, and error protection through the use of parity. These logical disks are in turn grouped together into a pool on which virtual disks are striped across. Greater parallelization (resulting in higher performance) and resiliency are achieved by striping a logical volume (i.e., virtual disk) across a group of RAIDs, which in turn stripe the data across multiple physical disks to achieve resiliency. This resource pooling abstraction also simplifies storage allocation by hiding the underlying physical storage device details from system administrators and avoids poor capacity utilization by allocating volumes efficiently and dynamically, with the appropriate amount of disk space (rather than entire disks) to host servers. In addition, modern disk subsystems leverage a virtualization technique named *thin provisioning* to further increase storage utilization by reducing the amount of allocated yet unused disk space within volumes. Thin provisioned volumes, also known as thin volumes, are volumes that present a virtual capacity to a host that is actually larger than its actual capacity. Thin volumes can have auto expand and auto shrink features to grow or reduce appropriately over time, in tune with the host server's application demands.

Another key advantage of virtualized storage disk subsystem is that due to the decoupling from physical location, data can be migrated from one volume pool to another. This aids in load balancing (e.g., alleviating overutilized devices) and attains better information lifecycle management (ILM) (e.g., moving frequently accessed data to a pool with faster devices such as solid-state disks). The subsystem executes data migration by making a copy of the data block in the target location and then updating its virtual to logical address mapping to redirect incoming I/O requests to the new location. Since the virtual address remains the same and the volume remains accessible the entire time, the data migration can be accomplished in a nondisruptive fashion.

47.2.3 SAN Storage Virtualization

SAN virtualization is able to reduce the cost and complexity of the overall storage network and improve performance and reliability. For example, a shared solid-state drive (SSD) can be placed in the SAN and used by multiple disk subsystems jointly, as though it is a local cache for fast data access. By shifting the storage virtualization functionality from host servers and disk subsystems, the storage capacity of the overall SAN can be managed by a logical central entity in an efficient way, since the aggregate resource pool can be shared seamlessly, which is transparent to the host servers.

As an example, IBM SAN Volume Controller (SVC) is a storage virtualization appliance that forms logical volumes from physical disks. Disk subsystems are connected to the SVC and all I/O access traverses it. Therefore, SVC functions as a gateway appliance between the host servers and the disk subsystems where all physical-to-virtual mapping and management are executed in a centralized fashion. This allows the system administrator to add/remove physical storage without affecting existing volumes since the virtual address remains unchanged.

SAN virtualization can be implemented in two ways, i.e., *in-band* and *out-of-band*. For in-band SAN virtualization, management, control, and data all share the same I/O path. In other words, all I/O data access traverses the management device, or SAN virtualization controller, such as IBM SVC appliance. In contrast, out-of-band solutions separate the SAN virtualization management from the data path, e.g., EMC Invista, which runs on SAN switches [4]. An additional software agent usually needs to be installed, and whenever an I/O request is initiated, the agent establishes a connection to the out-of-band SAN controller for data location lookups, and the actual data flow may go through a different path.

In-band and out-of-band SAN virtualization schemes are shown in Figures 47.5 and 47.6, respectively. In the in-band scenario, the centralized SAN controller will translate the logical location *A* to the physical location 1 and obtain the data on the server's behalf, while in the out-of-band case, the host agent will first inquire the logical–physical mapping from the out-of-band SAN controller and fetch the data next. Both SAN virtualization schemes are widely deployed in enterprise IT infrastructures. In-band solutions are usually easier to implement since no additional modifications are needed

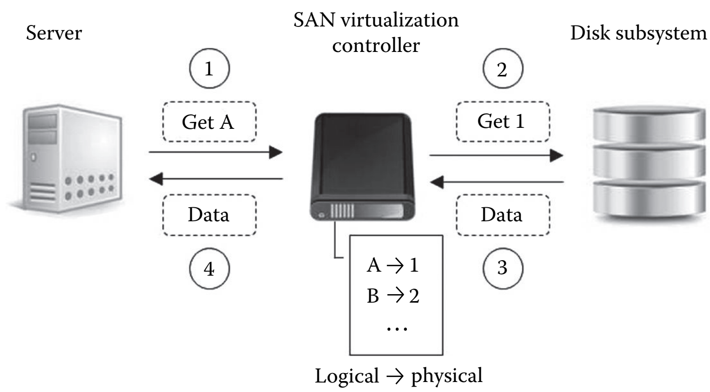

FIGURE 47.5 In-band SAN virtualization.

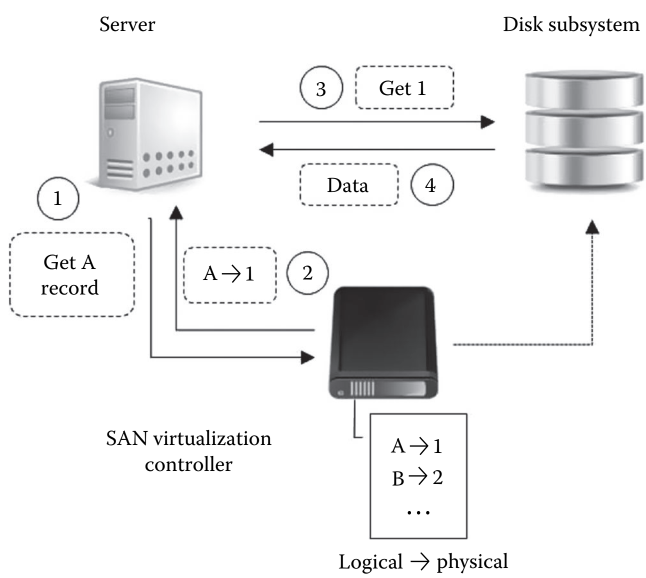

FIGURE 47.6 Out-of-band SAN virtualization.

on the host server devices. On the contrary, out-band solutions need a software agent installed on the host server whereas the SAN bandwidth is utilized more efficiently due to the separation of data and control flows.

47.3 Virtualization in Enterprise and Cloud Computing IT Systems

Enterprises utilize virtualization techniques extensively to build their scalable and reliable data centers. In traditional data centers, a single application usually resides in a designated server and the average server utilization is very low. Significant resource waste is due to the inflexibility of adjustment after the resources are allocated. In contrast, for modern data centers with virtualization, system efficiency can be remarkably enhanced by creating multiple VMs and consolidating them into a shared physical server to reduce space and maintenance cost (e.g., cooling). Meanwhile, improved performance can be achieved through the ease of resource sharing and portability across multiple VMs. Virtualization also enables faster IT solution deployment, e.g., hardware addition and replacement, and adaptive data migration, due to its flexible architecture and environment, and hence improves the enterprise business responsiveness. Therefore, the synergistic combination of platform, network, and storage virtualization serves as the technology engine to help enterprises achieve their agile and cost-efficient IT strategies.

Cloud computing is a platform of service provisioning in a flexible and on-demand manner. With cloud computing IT infrastructures, client users are able to focus on application development and business value creation by relying on the cloud service providers (CSPs) to establish the underlying IT infrastructure and actual job execution. Therefore, cloud computing shifts the hardware management and maintenance burden from client users and enjoys many eminent features such as elastic resource provisioning that propel its fast development and wide deployment in the IT industry. As shown in Figure 47.7, cloud computing infrastructure can be conceptually divided into compute and

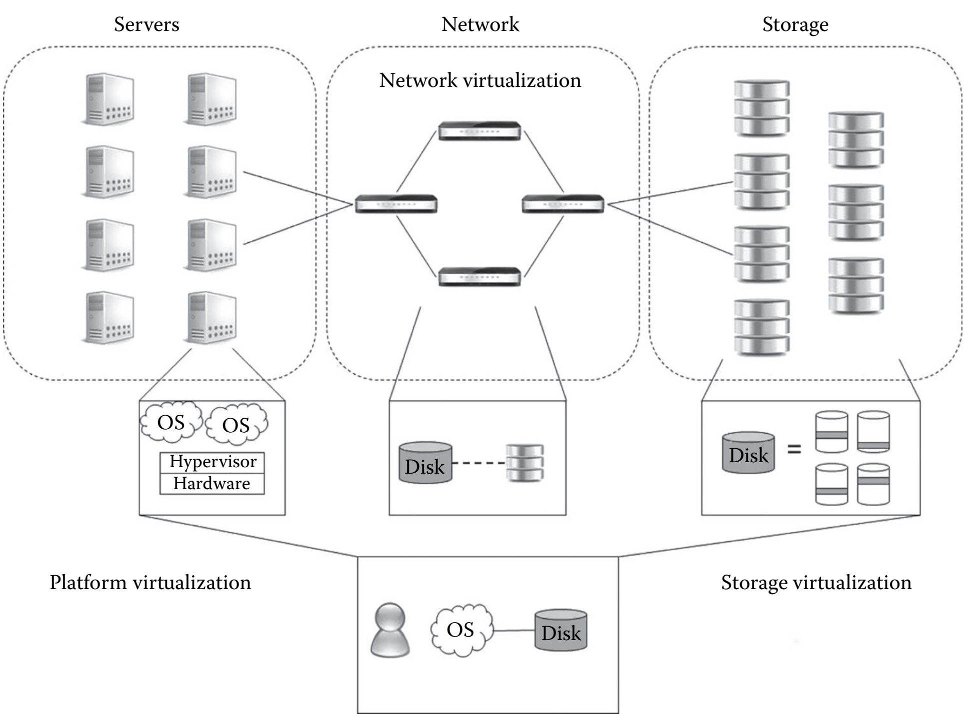

FIGURE 47.7 Virtualization in the cloud.

storage, which are interconnected via either Fibre Channel, IP networks, or gateway devices such as SVCs introduced in Section 47.2.

Cloud systems usually provide three types of on-demand services, i.e., Infrastructure-as-a-Service (IaaS), Platform-as-a-Service (PaaS), and Software-as-a-Service (SaaS). IaaS provides a pay-as-you-go model to utilize the cloud hardware resources, which allows users to specify the amount of CPU, memory, storage, and types of OSs, according to their application and business needs. For example, Amazon EC2 [2] provides a multi-tenant resource-sharing platform in the form of *VM instances*, and each instance is charged according to its CPU, memory, storage size, and the time duration it is leased. PaaS is an integration of both hardware and software infrastructures, e.g., Google App Engine [6] and Amazon Elastic MapReduce [3], which provide a convenient way for client users to develop and deploy their own business applications. SaaS usually provides an on-demand software service via a web browser, e.g., Google Gmail and Docs. From the cloud users' perspective, software development and upfront hardware cost can be saved and thus the CAPEX remains at a low level, compared to the conventional IT solutions.

Virtualization is *the* key enabling technique behind cloud computing systems to facilitate a flexible and scalable multi-tenant IT infrastructure. According to each user's application requirements, the cloud system can create multiple VMs, virtual disks, and connect them via a virtualized private network as desired. The resources allocated to multiple users are isolated while the scalability of each virtualized private environment is preserved. Cloud computing systems also leverage virtualization techniques for data migration and dynamic service provisioning to achieve both system resiliency and resource utilization efficiency.

47.4 Challenges and Research Issues

Despite the well-understood benefits and features, there are several remaining issues that need to be addressed to advance the virtualization techniques as well as the IT solutions based on them. We next discuss a few aspects of existing virtualization solutions as future research directions.

- *Virtual resource placement:*
  Due to the contention in cloud resource sharing, the overall system performance hinges largely on how virtual resources, such as VMs and virtual disks (VDisk), are placed on the physical servers. Obtaining the optimum resource allocation solution is usually computationally intensive and challenging due to its inherent combinatorial nature. In [31] and [34], the inter-VM traffic is considered and VMs with extensive mutual communication are allocated to nearby physical machines to alleviate network congestion. A joint VM and VDisk placement scheme is proposed in [35]. The authors of [27] consider the energy expenditure in VM placement where the resource allocation solution is adjusted based on power costs as well as application utilities. The chain effect of VM migrations is studied in [37], where a dynamic migration strategy is proposed for overcommitted cloud infrastructures. Specifically, the authors consider the statistical traffic patterns of VMs for multiplexing to avoid future VM migrations induced by the ongoing VM migration, and thus the number of migrations is reduced.
- *Multitenancy:*
  Most virtualization techniques require a centralized entity that provides the mapping between logical resources and physical resources. This inevitably introduces a single point of failure that triggers concurrent service disruptions for many clients in case of a failure. For example, during a reported outage of Amazon EC2 cloud [1], many customers such as Netflix, Instagram, Pinterest, and Heroku were affected simultaneously. In addition, while the system utilization can be remarkably improved, sharing application data of many different clients on the same infrastructure requires stringent security and privacy protection mechanisms. Therefore, how to share the physical resources in an efficient and trustworthy manner for multi-tenant virtualized systems remains an open question and deserves further investigation. For example, in [33], the

authors identify emerging security and privacy threats in a virtualized cloud environment due to the physical resource sharing among multiple VMs, and several mitigating solutions are proposed. A general framework based on an operational transformation model is designed in [29], which allows customers to collaborate securely on untrusted cloud servers.

- *Skyrocketing I/O demands:*
  Many virtualization solutions such as platform virtualization allow each physical system to host multiple VMs that share the same underlying hardware. However, such consolidation yields more intensive I/O demands that impose a remarkable burden on the I/O devices as well as the network and SAN switches along the I/O path. For example, if many VMs on the same server host database applications, voluminous I/O requests will be generated concurrently on the I/O path. Therefore, designing novel I/O techniques and architectures to accommodate large amount of (possibly bursty) I/O requests is imperative.
- *Software licensing:*
  Virtualization introduces new challenges from the software licensing perspective. With virtualized machines and platforms, the auditing and management of software license becomes more complex and difficult, especially due to the fact that VMs can be created and deleted at any time.
- *Root cause analysis:*
  As a cost of flexibility, virtualization adds a layer of indirection, and it is not uncommon that multiple layers of virtualization are implemented at different places within the overall IT system, which makes root cause analysis and network diagnosis more challenging. Information provenance and forensics in a virtualized environment are active research topics in the community, e.g., [26,30].
- *Chargeback policy:*
  In traditional IT infrastructures, the charge levied to each client can be easily computed by measuring the amount of allocated resources, e.g., the number of servers and the capacity of storage. However, in a shared virtualized environment, it is difficult to attribute the hardware expenditure using conventional methods due to many layers of abstraction and indirection. The actual hardware expense as well as the management cost should be charged to client users appropriately, which are only willing to pay for the amount of virtual resources that they requested. In [22], an integrated toolkit is designed to support fine-tuned cost models and charge policies of enterprise with shared IT infrastructure and heterogeneous users. Designing a flexible and profitable chargeback policy remains one of the key challenges for many CSPs with virtualized multi-tenant architectures.

47.5 Conclusions

Virtualization provides an additional layer of indirection by abstracting the physical resources into a logical resource pool, in order to attain efficient system utilization and flexible manageability. In this chapter, we provided an overview of various types of virtualization techniques utilized in current IT systems. Specifically, we introduced platform virtualization, network virtualization, storage virtualization, and their applications in cloud computing IT infrastructures. While virtualization has been widely deployed in many emerging IT systems, challenges such as multi-tenancy and software licensing issues remain as future research topics and need further investigation.

48.1 Introduction

The concept of cloud computing has received widespread attention since its emergence in about 2007 and has become an important option for the provisioning of IS/IT infrastructure, platform, and applications. In 2012, the U.S. National Institute for Standards and Technology defined cloud computing as

> a model for enabling ubiquitous, convenient, on-demand network access to a shared pool of configurable computing resources (e.g., networks, servers, storage, applications, and services) that can be rapidly provisioned and released with minimal management effort or service provider interaction. (Mell and Grance 2011, p. 2).

Moreover, the NIST definition states that cloud computing, in its purest form, should exhibit the following "essential characteristics":

- *On-demand self-service*: users can access cloud computing capabilities as needed, without requiring human interaction.
- *Broad network access*: Cloud computing services should be available over the Internet and accessed through standard mechanisms, such as a web browser, which allows use by heterogeneous client devices including smartphones, tablets, laptops, and workstations.
- *Resource pooling*: Cloud computing capabilities are pooled to serve multiple users (a multi-tenancy model) and are assigned dynamically to users according to demand. As a result, users have no control or knowledge of the location of the underlying resources.

- *Rapid elasticity*: Computing capabilities can be instantly provisioned and released, typically automatically, to provide rapid and unlimited upward and downward scaling in response to computational needs.
- *Measured service*: Cloud computing services are metered according to service-appropriate metrics (e.g., storage, processing, bandwidth, number of active user accounts), with automatic monitoring of usage levels, and priced according to use.

While the combination of these characteristics is new, many of the underlying concepts of cloud computing go back to the origins of business computing in the 1950s. Unfortunately, a combination of semantic ambiguities and vendor opportunism has resulted in the term "cloud computing" being used very broadly to describe many variations of computing, storage, and network services across various "off-premise" deployment methods. From the business and user perspectives, cloud computing is an approach in which hardware, software, network, storage, and server resources can be accessed "as a service" from a third party, thereby eliminating the large up-front expense of purchasing the necessary components to build the required technical environment in-house. Additionally, cloud computing can refer to the virtualization of in-house resources, creating an internal infrastructure that maximizes the efficiency of proprietary hardware.

From a technical perspective, cloud computing is a style of computing that employs virtualization methods to create dynamically scalable IT resources. These can be offered to users as a service at a comparably affordable price as a consequence of the economies of scale that cloud service providers can achieve. Taken together, these business and technological perspectives have contributed to the rapid emergence of cloud providers over the past 5 years and the rapid adoption of cloud services. Cloud computing is becoming a computing style of choice by users, a dominant mode of computing within small- and medium-sized businesses, and a key component of the computing portfolio of large enterprises. Based on their extensive survey of cloud adoption practices at over 1000 firms, Willcocks et al. (2011) found that nearly two-third of executives viewed cloud computing as an enabling business service and IT delivery model that was driving innovation in organizations. In short, significant adoption of cloud computing has become inevitable (Seely Brown 2012) and is already well underway.

48.2 Underlying Dimensions

The breadth of resources and the variety of deployment models offered by cloud computing vendors contribute to its complexity. The following section lists the major categories of cloud computing commonly offered today with brief descriptions.

48.2.1 Domains of Cloud Computing

Infrastructure-as-a-Service (IaaS): "Infrastructure" typically refers to the tangible hardware components that are required in order to create a computing environment. In order to create computing and storage platforms, companies have traditionally built their own data centers that include the necessary servers, data storage units, power supplies, environmental controls, and other hardware components that provide the foundation for all their computing capabilities. In large companies, these are often large, dedicated centers that require full-time operations personnel and dedicated physical space. In smaller companies, this may simply be a "computer closet." Either way, infrastructure requires capital investment that must be kept operational and up-to-date in order to support the computing needs of the firm.

IaaS refers to the acquisition of these infrastructure capabilities as a "pay-for-use-service" on a contractual basis from a third party, in accordance with the essential characteristics as defined earlier. This eliminates the need for costly physical assets and operational expenses, as well as the need to hire

experts to configure, operate, and maintain them. With IaaS, a company can host its enterprise applications on virtualized hardware that they never have to see, update, or troubleshoot.

Platform-as-a-Service (PaaS): In order to understand what is meant by PaaS cloud computing, it is first necessary to understand the concept of a computing platform. In software terminology, a platform is the underlying middle-layer code upon which applications and their interfaces are built. For example, the operating system on your laptop (such as Microsoft Windows or Mac OS) is an example of a computing platform. To simplify, we can think of a computing platform as simply an environment upon which software applications are launched and run.

When translated to cloud computing terminology, "platform" has been used to describe several different types of computing capabilities and uses, and this definition continues to evolve. PaaS refers to "renting" an operating platform, such as Force.com or Microsoft Azure, on which a firm can build customized software applications to meet its specific needs. Procuring a cloud-based platform also implies that the cloud vendor will be providing the infrastructure necessary to support the platform, so you can think of a cloud platform as the delivery of IaaS with an additional layer of functionality upon which a company can develop or purchase compatible software solutions. Cloud-based platforms are designed with software developers in mind and so provide the tools and support that developers need in order to create agile, scalable applications that typically are also mobile device and social media enabled. PaaS cloud computing remains one of the less developed areas of cloud computing. Over the coming years, its definition will likely evolve and become inclusive of more computing functionalities such as database management, business activity monitoring, and corporate governance (Mitchell Smith et al. 2012).

Software-as-a-Service: Cloud-based software-as-a-service offerings have been around for over a decade and have become the most commonly consumed cloud service genre across consumer and enterprise users. Essentially, SaaS delivers software functionality as a service, rather than as a packaged product that is licensed for use. The functionality is "bundled" with the underlying infrastructure needed to host and run an application and the operating platform on which the application is built. Examples of SaaS solutions in the end-user and consumer markets include web-hosted email providers (such as Gmail or Yahoo! Mail), search engines, Quicken, Pandora, and Netflix. Common enterprise SaaS offerings include Salesforce.com, Workday, and Radian6, an analytics tool used to gauge conversation and sentiment trends via social web conversation analysis. With SaaS, functionality is delivered remotely to registered users over the Internet via a browser. The service is paid for according to the terms of a contract (generally per user per month). Instead of consuming hard drive space and processing power on a native device such as desktop computer or laptop, SaaS solutions are provisioned remotely by a vendor's virtual infrastructure. Additionally, SaaS solutions are constantly being updated as its developers are fixing bugs and building/releasing new features and functionalities. These improvements to the application are automated for the end user and do not require a new version purchase or lengthy update downloads.

Business Process-as-a-Service: BPaaS remains the least mature, but potentially most business beneficial area of cloud computing. An extension of business process outsourcing (BPO) that incorporates cloud computing principles, BPaaS involves the provisioning of highly standardized end-to-end business processes that are offered through on-demand, pay-per-use, and self-service provisioning models. Currently, the most common process capabilities being sourced via this model include employee productivity, employee source to pay, payroll, customer contact to incident resolution, hire to retire, and order to cash (Karamouzis 2012). The underlying resources and capabilities used to provide the business processes are shared by multiple customers, with possible additional benefits that can emerge from pooling data across these multiple customers. Ried and Kisker (2011) suggest that "BPaaS in many ways represents the culmination of cloud based innovation" (p. 4). It is possible that future innovations in BPaaS services will evolve toward the concept of "Complex Adaptive Business Systems" as articulated by Tanriverdi et al. (2010).

48.2.2 Deployment Methods

Now equipped with a working knowledge of what cloud computing and the general categories of cloud services, the next step in fully understanding cloud technology is to compare and contrast the ways in which these solutions are delivered.

Public Cloud Platforms: The public cloud generally refers to a cloud service that is delivered over the public Internet and is shared by multiple users or "multitenant." Examples include Amazon Web Services, Google Docs, Facebook, and Salesforce.com. Generally, users subscribe to a public cloud service (such as an application or storage space) and then, instead of being supported by an internal virtualization network, users can access that account anywhere from which there is a public Internet connection.

Private Cloud Platforms: The private cloud differs from the public cloud much the same way that an intranet differs from the Internet. Essentially, a private cloud is created with a company's proprietary resources. However, it uses cloud computing techniques such as virtualization and data center automation in order to achieve the elasticity benefits that are one of the major advantages of public clouds but also the efficiency and productivity benefits associated with cloud-based provisioning. Generally, private clouds provide their owners with greater control over their capabilities and are often cited as providing a higher level of security (Accenture 2010). Companies can either invest in and create this cloud independent of any third-party vendor or utilize third-party services and the "pay-as-you-go" model with private cloud vendors. Examples of such a vendor are EMC's VMWare, a company that offers enterprise software virtualization products, and Pogoplug that offers products that allow a personal computer to become a web-based file sharing server, pooling storage capacity across all computers within a single company and creating a central location for file access.

The Chief Information Officer (CIO) of a global construction company that was an early adopter of cloud computing shared the view that the biggest difference between a public cloud and a private cloud is whose balance sheet includes the infrastructure asset. The idea behind this statement is that if the technology and capabilities of the cloud are the same or similar internally or externally, then there is no functional difference in regard to business processes (HBR Analytic Services 2011). Although this may be true for a company that does not have the need to create flexibility in its IT operations beyond what can be provided by a cloud vendor, for a company that competes in part through its ability to provide cutting-edge customer service, tracking, supply-chain management, or other functions that rely on increasingly improving IT capabilities, this may be less likely. Private clouds, although generally more expensive to build and maintain than public cloud services, can provide a company with the ability to create their own customized solutions above and beyond what is currently available in the vendor market.

Community or Virtual Private Cloud Platforms: A community cloud refers to a cloud that is hosted on the public Internet but is not fully multitenant. Rather, it is shared between a restricted community of firms or users, thus addressing the concerns of security and/or verifiability of the geographic location of the data. One major downfall of using a private cloud is the lack of economies of scale that arise from the efficiencies inherent in providing services to the large number of users that tap into public cloud solutions. In industries where similar businesses use private cloud computing capabilities, it is often advantageous to pool these resources in order to achieve some of the economies of scale that are lost in single-firm private clouds. Generally, these community clouds integrate numerous private clouds, using the unallocated resources from user machines to create a virtual data center.

Hybrid Cloud Platforms: Hybrid clouds refer to a type of cloud computing deployment that uses a combination of more than one delivery method, such as private and public cloud services. Typically, firms that are highly concerned with security issues and/or have legacy applications that would be too costly to move to public cloud computing services will maintain a portion of their computing capabilities within a private ecosystem and utilize public software and platform clouds to enable other business processes. Another reason hybrid clouds are popular is that they provide a means

from which enterprises can remove data quickly from a public cloud, in response to either a pending security threat or complications with a vendor.

48.2.3 Location Types

There are three different ways that clouds can be located, each with its own set of capabilities and purposes:

On-site: An on-site cloud is a cloud that is located entirely on the premises of the user. The cloud can either be owned by the company itself or it could be the property of a third-party vendor that installs, maintains, and services the hardware. The latter option allows companies to have the benefits of private cloud computing without the hefty capital expenditure of purchasing the equipment. Hitachi Data Systems is a vendor that originally offered cloud computing services for telecommunication companies in the public cloud. However, having identified and understood the hesitation of executives in the telecommunication industry to move private consumer information into a public cloud, they began offering on-site, private clouds that they locate within the client company's own firewall.

Dedicated: Like an on-site cloud, a dedicated cloud serves only one client—however, the cloud is located in the provider's facilities. Companies can obtain dedicated infrastructure for their own use, instead of sharing with other "tenants." This allows a company to have greater control over the infrastructure—for example, if a company is utilizing a dedicated server to host its portfolio of corporate websites, then it would be able to select what operating system the website will use and what sort of security protection (such as encryption capabilities and firewalls) the server will provide. In general, a dedicated cloud gives the client more ability to customize the machine in accordance with its own needs (Loebbecke et al. 2012).

Shared: Shared clouds are the most commonly used type of cloud. These are located off-site (generally in the vendor's facilities) and allow multiple clients to utilize the same resources (Loebbecke et al. 2012). There is limited customization with this location method, but it is generally a less expensive option than on-site or dedicated clouds.

48.3 Impact on Business Practice: Applications of Cloud Computing and Their Outcomes

As more companies adopt cloud computing successfully to minimize cost, increase agility and standardization, and bring products to market faster, other firms across the spectrum of size, industry, and globalization are taking interest (Abokhodair et al. 2012). Although the potential benefits of cloud computing are compelling, managers must be aware of what objectives they are trying to accomplish with cloud technologies and develop effective management practices for eliciting and maintaining the intended benefits.

48.3.1 Benefits of Cloud Computing

The most commonly cited benefits offered by cloud computing are significantly reduced IT fixed costs and IT capital assets, increased speed of deployment of IT services, and greater flexibility or "elasticity" of IT services provisioning (Accenture 2012; Harris and Alter 2010; Iyer and Henderson 2012; McAfee 2011). Short-term variable cost reductions may also emerge from reductions in data center operational costs, IT operations, maintenance and support staff, electricity usage, and software licensing fees. Large, established companies can also take advantage of these savings by substituting internally developed or acquired assets with infrastructure, platform, and application services that are hosted in the cloud. Likewise, companies that are just entering new markets can experience decreased barriers to entry due

to the fact that they have instant access to "world class" computing capabilities at affordable prices. Beyond cost, however, cloud computing offers other important areas of benefit for business organizations. Drawing from their research on early adopter companies, Iyer and Henderson (2012) identified six "benefit patterns" that companies had achieved from leveraging cloud computing capabilities: increased business focus, reusable infrastructure, collective problem solving, business model experimentation, orchestrating business partner dependencies and the "Facebook effect" of leveraging mobile devices, social networking, real-time data, and user-driven content generation. The aggregation of perceived business benefits across a wider range of adopters reveals the following primary areas of impact:

Flexibility: Cloud computing can offer flexible resources to companies that experience seasonal or sporadic increases in computing capacity needs. By offering these resources in such a way that is immediately elastic, companies need not invest in extra infrastructure just to support periodic bursts or suffer from overloading due to insufficient resources. These two factors not only add to the potential cost savings of a firm but also help to negate the risk of unsatisfactory service due to a lack of capacity. Due to the nature of cloud computing, new capabilities can be quickly implemented and deployed, increasing the speed in which a firm has access to technologies that assist in creating and delivering products, thereby increasing the speed in which these products get to market.

Standardization: Another compelling benefit of cloud computing is the ability for a large corporation to be able to standardize applications across previously segmented and siloed parts of the firm. Oftentimes, the apparent needs of different departments/regional locations within the same company give way to employing multiple legacy applications that are not capable of sharing information with one another, creating silos, communication difficulties, and compromising business intelligence. The task of extracting the data in these applications and moving them over to a new integrated system that attempts to solve these issues can be daunting and expensive. Cloud computing offers the possibility of deploying such a shared platform with greater speed, less expense, and less user resistance than creating an internal system.

Business intelligence and big data: Business insights and analytics tools powered by public and community clouds are becoming an increasingly popular means to access and analyze the vast datasets now available to business organizations. For example, some cloud analytics vendors create detailed geographic and demographic profiles by analyzing and interpreting the click behavior and interactions of millions of online consumers. By tapping into the resources generated by public clouds, firms are able to attain access to more granular (and therefore accurate) information than they would have otherwise. Some vendors, such as APTARE, leverage a community cloud in order to provide its members with analytical data regarding how well they are optimizing their data storage resources. The company, while keeping each individual community member's information private, is able to study and compare how well a firm is utilizing its resources compared to other members of the community with an infrastructure of similar size and scope.

Companies that develop their own internal clouds can use these capabilities to offer innovative products and services in addition to their core offerings, gaining a competitive advantage in the marketplace.

Enabling focus on core business competencies: In an ideal world, all IT systems would effectively act as enablers of core business functions, creating a more efficient and effective workforce. Too often, however, technology begins to create operational boundaries, limiting the very employees that it was implemented to help. Salespeople in the field are not able to provide customers with immediate information without access to their computers; IT professionals are distracted from their core duties when expanding technological capabilities to a new branch location; customer service agents cannot deliver speedy service when they are required to search through multiple, nonintegrated databases to gather basic information.

Cloud computing can offer solutions to such problems through multi-device access, anywhere anytime access, and standardization across all users. Salespeople can answer customer questions in real

time via mobile cloud software services, branch openings are simplified by utilizing cloud computing vendor capabilities for immediate expansion, and SaaS offerings may provide integrated databases and immediate knowledge-sharing capabilities. In such scenarios, employees are empowered to focus on what matters most to the core business, whether that be customer service, knowledge expertise, or something else (Iyer and Henderson 2010).

48.3.2 Management Practices for Achieving Benefits from Cloud Computing

Although the possible business benefits of cloud computing are significant, managers of firms that intend to deploy cloud computing for business benefit must understand that cloud deployment is much like any other IT-enabled business process in that it must be carefully analyzed, planned, deployed, and monitored after implementation. Because cloud computing is an emerging technology with low barriers to adoption, it may be easy to fall into the trap of experimentation and speculation. Before moving to a cloud solution, managers must perform a comprehensive analysis of benefits, costs and risks, vendor due diligence, and develop compelling business cases built on appropriate, verifiable metrics (Herbert and Erickson 2011).

Although there are clear steps that should be taken before any business leader embarks on a journey to the cloud, research shows that managers who have had more than 5 years of experience with cloud computing are convinced that the benefits are greater than the risk (HBR Analytic Services 2011). Experience with cloud computing cultivates effective management capabilities, which in turn engenders confidence. Recent research showed that only 4% of senior managers in companies with more than five years of experience perceive that the risks of cloud computing outweigh the benefits (HBR Analytic Services 2011).

48.3.2.1 Understand the Market and Your Current IT Environment

Before undergoing a switch from traditional to cloud computing solutions, managers must understand thoroughly the rationale for this decision. In what areas does the firm need improvement? Is the market faced with an influx of new entrants that are more agile and more rapidly bringing products to market? Does the company need to standardize its processes in order to increase productivity and minimize the learning curve for cross-functional teams? Are legacy applications outdated and difficult to modernize?

A thorough understanding of the ways in which cloud computing is currently being used in your industry is necessary before coming to conclusions regarding how best to incorporate it into your company's current operations. This process is further aided by mapping out the company's IT infrastructure, platform, and application ecosystem. What business processes are supported by legacy applications? What is involved with moving these processes to cloud-based solutions? Is the cost of the transition sufficiently outweighed by the expected benefits gained from increased efficiency and productivity? How strong are the data used to support the decision?

Investigating industry best practices with the cloud and how conducive the firm's current technology management capabilities are to moving to a cloud environment will bring clarity to the adoption decision. Although the possible benefits of cloud computing are numerous, companies will need to have a clear vision for why they are moving to cloud computing and what challenges and/or synergies it will encounter with its current ecosystem.

48.3.2.2 Define and Manage the Intended Outcomes

Because of the extent of hype surrounding cloud computing, it may be easy to assume that moving a company over to cloud solutions will reduce costs and increase agility, but in order to get the most out of cloud-based solutions, managers must be specific regarding the intended processes they intend to improve, cost and revenue metrics, and other business outcomes. Managers cannot simply make the switch to cloud computing because it is trending in the industry or because they expect certain outcomes that are loosely defined. This goes beyond identifying areas of opportunity to creating a road map

that describes hard objectives with useful measurements, the stakeholders involved, how the change will affect them, and the identification of who in the company will be responsible for ensuring that the objectives come to fruition (Peppard et al. 2007).

Involve stakeholders and stakeholder representatives in the formation of this plan in order to identify and address concerns that may not be apparent. Including those impacted by a change to a cloud computing solution in the decision itself will not only give managers greater clarity regarding the likely consequences of the change, but will also help to create buy-in from different user groups.

48.3.2.3 Define and Manage the Necessary Changes

If the current IT ecosystem is thoroughly understood and if that information aids in the selection of a cloud solution, deployment model, and vendor, then much of the legwork for defining what actual changes need to happen for a successful transition is already done. Examples of such changes could include redefining certain professional roles, training personnel on a new software solution, or redesigning a particular business process to be aligned with standardization goals. Whatever the change, managers must identify it and assign the management of it to a particular owner. These changes should be linked to their intended business outcome and should follow a plan that includes a timeline, milestones, and risk mitigation considerations.

In order to successfully create a realistic timeline and properly put into place mechanisms of risk mitigation, stakeholders must once again be consulted and considered. Who will be affected by this change? What pending projects are reliant on the legacy application that is being eradicated? What technological capabilities will be lost if all data centers are consolidated and an IaaS solution is deployed? What contingency plans are in place to help business processes continue in the event there is a hitch? What long-term cultural and organizational changes will result in this new business model?

48.3.3 Cloud Computing Risks

Although the possible benefits from switching to a business model that incorporates cloud computing has the potential to be dramatic, there are also many risks and challenges involved in the decision, which conscientious managers must address.

48.3.3.1 Confidentiality and Privacy of Data

What managers across the globe are concerned with is the threat of data privacy and confidentiality breaches (Accenture 2010). In addition, global companies may need to contend with differences in privacy laws depending on where they conduct business and prepare for subpoenas, searches, and seizures as permitted by local law. As we progress into the twenty-first century, the laws and regulations surrounding the use of cloud computing services will need to evolve with these developments. Firms will need to ensure that they remain under compliance and are protected. Before entering into new global territories, firms needed to closely scrutinize the liabilities that they may be subject to as users of cloud computing. They will also need to regularly audit their vendors to ensure that they are regularly iterating the development of their security measures to keep up with constantly evolving threats.

48.3.3.2 Market and Vendor Maturity

At this point in time, the cloud computing market is relatively immature, so there are constantly emerging vendors that are vying for market share. Although newer entrants may appear to offer better deals or other benefits, there is inherent value in a vendor that has proven its reliability as a trustworthy business partner. If a company's day-to-day operations rely on applications, stored data, or other capabilities that are powered by the cloud (as they likely will), then it could be potentially disastrous for that cloud to incur some sort of technical failure.

Relatively young firms and new entrants dominate the market space of cloud computing providers. This is particularly the case with the most innovative cloud service firms, many of which are new

ventures that are dependent upon venture capital for financial stability, whose offerings are relatively new to market and are relatively unproven, and whose customer base is small when compared with the long-established vendors of comprehensive enterprise systems. The overall immaturity of this sector creates greater risks and concerns for adopting firms and will require robust due diligence in vendor evaluation and contracting (Phifer and Heiser 2012).

48.3.3.3 Integration with Existing On-Premise Systems

A significant challenge for many firms relates to the necessity to integrate data between traditional on-premise systems and cloud-based services in order to provide for data standardization and process coordination. One of the key benefits of tightly integrated enterprise resource planning (ERP) systems was their embedded support for data integration and master data management. The potential shift from, or augmentation of, these integrated ERP systems with specialized SaaS services creates potential risks of data silos and data inconsistencies (Radcliff 2012).

48.3.3.4 Low Maturity and Consistency of Local and Global Regulations

Another potential challenge for the adoption of cloud computing is the immaturity of regulations that govern various critical aspects of cloud computing services including vendor responsibilities, service-loss accountabilities, data loss prevention, and privacy protection. This sphere is further complicated by differences and inconsistencies in the prevailing policies and regulations across major regions of the world.

48.3.3.5 Reduced Control over IT Demand

Another potential risk associated with the availability of apparently more affordable, on-demand, direct access by users to unlimited computing resources is that demand and consumption of these services can grow exponentially, resulting in significant increases in overall computing costs. Contrast the likely behaviors when users must operate within a fixed storage allocation (e.g., mailbox, file share, or data archive quota) versus behaviors when offered apparently unlimited storage as a service. Combine this with the ability of business unit executives to independently contract for cloud services directly with cloud providers, and the potential for rapid escalation of demand and consumption of IT services emerges. For better or worse, IT units and traditional IT management approaches played a "demand management" role that served to control rising demand and consumption of IT services.

48.3.3.6 Vendor Reliability and Long-Term Viability

Any company that is considering moving critical computing capabilities to the cloud must thoroughly consider the risks of vendor failure. The disaster recovery and business contingency measures that a company should take to protect itself against possible vendor outages are not unlike those it would take to protect against failure of "on-premise" computing infrastructure. Data centers built internally are not immune to risk and must include contingency plans in the event of an unexpected interruption, whether it be from a natural disaster, faulty equipment, malevolent interruptions, or some other occurrence.

However, because of the media attention that cloud computing outages have received in the last couple of years, the actual risks associated with cloud computing reliability have been somewhat exaggerated. A cloud vendor's reputation and long-term viability are highly dependent on its reliability, and so cloud vendors have a string motivation to ensure that their services are backed by robust technologies, processes, and management practices. Although there are certainly examples of large failures such as Amazon E2C's 3 day outage in 2011, there is also evidence of solutions that have thus far proven to be more reliable than their in-house counterparts. For example, Google's Gmail-enabled email services achieved 99.984% uptime in 2010—making it approximately 32 times more reliable than the average enterprise email system (McAfee 2011).

This is not to say that a loss of service is not a serious threat for companies that rely on cloud computing capabilities. However, proper steps can and should be taken to mitigate the potential consequences

of a system failure. Netflix is an example of a company that understands this principle and has truly integrated it into the DNA of its operations. When Amazon's cloud services famously went down in the spring of 2011, Netflix was able to continue to serve its customers uninterrupted because it had tested its systems for this contingency using an internal interference system it had built dubbed "Chaos Monkey." The system was designed to randomly attack subsets of the company's technology environment. These built-in attacks required all of Netflix's operative processes to develop adequate and immediate contingency plans, ensuring that the company was thoroughly prepared for an outside threat (McAfee 2011).

Beyond temporary services outages, a greater concern for cloud adopters is the long-term financial security and viability of highly innovative cloud service providers, many of which remain at the "early stage venture" of the business lifecycle, dependent upon investment funds for operating capital, and desperately striving to achieve the level of market success to ensure their survival and prosperity. Cloud adopters will need to conduct diligent analysis of the financial security and long-term viability of these highly innovative but immature cloud service providers.

48.3.3.7 Security

Skeptics of cloud computing often refer to the risks associated with off-premise cloud computing vendors maintaining the levels of security necessary to protect critical capabilities and proprietary data. These critics maintain that on-site data centers are superior in this regard due to the fact that the company itself controls them. This logic, however, is questionable at best. Cloud service providers are aware that their long-term viability is dependent on mitigating security breaches and consequently will typically dedicate far more resources and expertise to establishing and maintaining a highly secure environment than a typical client company would independently. That said, firms that have adopted cloud computing must manage the business risks associated with that decision and develop business continuity plans (backup plans) in the event the cloud service is inaccessible, or data are compromised, and develop appropriate data recovery processes. These plans should be reexamined periodically to ensure that the considerations remain relevant and complete.

In the absence of effective guarantees about service and compensatory damages from suppliers, and the absence of legal precedent in these areas, some firms have addressed the potential loss, risk and liability issues by taking out cyber-liability insurance (HBR Analytic Services 2011). Users can also manage this risk by dealing with well-established vendors, avoiding new vendors that have not yet proven reputations in the market. A clearly defined exit path should be developed to prepare for an event in which the vendor suffers some unexpected loss, i.e., bankruptcy or a natural disaster (Stroh 2009).

48.3.3.8 Vendor Lock-In

Firms need to pay special attention to the construction of their clouds, not just in the interest of building the most relevant and cost-effective solution, but also to mitigate the threat of too much vendor control. Vendor lock-in can come in a variety of forms: lengthy and binding service contracts, applications built with proprietary Application Programming Interfaces (APIs), voluminous data storage costs, and hefty switching costs resulting from an ecosystem dominated by one vendor. However, as the cloud computing market grows, firms have an ever-increasing pool of vendors to choose from and should leverage their buyer power to create flexible solutions to minimize these threats.

The first step for any firm that is considering deploying a cloud solution is to build a blueprint of the desired ecosystem. This blueprint should consider what services are necessary, required storage capacity, operating requirements, where user training would be needed, and what elements of design are required for enabling seamless portability of public or community cloud data to the private cloud (and vice versa). Once a firm has a holistic picture of its service needs, it should consider how best to transition from existing assets and resources to the proposed cloud platform.

After taking a comprehensive examination of how the firm intends to use the cloud to satisfy its immediate and longer-term needs, it will be prepared with the right set of questions to present to vendors. For example, if the firm intends to build custom applications, it should consider whether or not

its PaaS vendor offers APIs that allow for app transfer to a new platform. In 2011, Google's App Engine enacted a sudden price increase, but because the applications built using this platform could not run anywhere else, firms had to weigh the cost of redevelopment against the cost of continuing to stay with App Engine. Users of PaaS offerings should also consider the type of code used to build applications, since some code is less expensive to alter than others (Gigaom 2011).

Considerable time should also be given to the negotiation of contracts, service agreements, and termination clauses. Of particular concern are the agreements around data portability. If possible, firms should diversify their cloud environment enough to limit reliability on any one vendor. Cloud vendors should be required to be transparent with their own ecosystem to ensure that customers are not unknowingly using third-party vendors that have not been appropriately vetted. As the market goes through a familiar pattern of mergers and acquisitions in the coming years, firms will need to dig deeper to uncover potentially problematic interdependencies in their proposed cloud ecosystems; otherwise, the diversification of vendors will not have the intended effect (White et al. 2010). By performing due diligence in this regard and leveraging buyer power to obtain preferential contracts, firms can hedge against multiple varieties of vendor lock-in.

48.3.3.9 Uncertainty around Return on Investment

It might be easy to get swept away in the hype around cloud computing. But like any major business decision, detailed analysis must precede any decision-making. First and foremost, there must be clearly defined benefits that are the intended outcome of the cloud migration. Without understanding *exactly why* a firm is considering a move to the cloud, a proper analysis (including opportunity costs and alternative options) cannot be performed. Once these intended benefits are articulated and included in the business case, however, firms should still rely as much as possible on hard metrics instead of speculative hunches. Tangible costs of the current environment should be compared with a holistic assessment of the costs of transition to cloud-based alternatives, including training, losses from temporary lapses in efficiencies, potential client attrition during the early stages, the added expense of hiring personnel to maintain vendor relationships, and the cost of the vendors themselves.

Depending on how a firm intends to use the cloud and the business benefits it hopes to gain, it will most likely need to develop hypotheses for the financial impact of these benefits. Where hard data do not exist, the hypotheses should be tested in microexperiments in order to avoid making larger, faulty assumptions. For example, if an insurance company believes that moving its customer data to the cloud would improve accessibility for its adjusters and therefore boost the speed of claim resolution and overall customer satisfaction, it could conduct a geographic experiment wherein a small subset of its covered locations are shifted to the cloud. This hypothesis could then be tested and proved (or disproved) before making a significant, company-wide transition (Harris and Alter 2010).

As hinted at in the previous example, return-on-investment, although a popular metric, may not be the best lens through which to view a cloud transition. For example, if one of the intended benefits is to improve employee collaboration or to become more agile in an increasingly dynamic marketplace, attaching a realistic Return on Investment (ROI) number may prove futile. However, the business impact of these improvements may be significant and should not be overlooked when making a case for cloud initiatives. Once again, experimentation and hypothesis testing can be very valuable for evaluating these assumptions and avoiding misguided or lofty predictions.

Finally, firms should ensure to carefully consider the various pricing models of the proposed vendors and evaluate the implications of these in the event of anticipated business growth and broader strategic goals. A thorough examination of available vendors should consider not only capabilities and lock-in potential, but whether or not their pricing models are aligned with the company's strategy (Stroh 2009).

48.3.3.10 Resistance from Executives, IT Managers, and Users

A thorough business case analysis should incorporate securing executive team support for moving critical capabilities to the cloud. However, studies show that IT professionals and business professionals tend

to view the risks and benefits associated with moving to the cloud quite differently, and so the same pitch may not be effective across the board (Willcocks et al. 2011). Namely, IT professionals tend to see the threat of lock-in as much more looming than their business counterparts, who in turn are more skeptical of the potentially negative impacts of *not* moving to the cloud. In addition, IT managers tend to be much more conservative regarding the expected benefits of the cloud and the time horizon necessary for attaining these benefits. The gaps in risk perception and expectations between business and IT staff members can potentially cause tension during the shift to the cloud, causing undue strain on the transition (Willcocks et al. 2011).

An effective way to manage this likely divergence of views is to build a cloud strategy team that is cross-functional, including members from the executive team and multi-department managers, including business and IT representatives. Additional valued members of this team would include law experts, innovation specialists, and managers adept at instituting new processes. Such cross-functional teams can do much in terms of bridging the gaps between the business and technology sides of the firm, creating a holistic and realistic cloud strategy, and earning buy-in from key company players (Harris and Alter 2010).

48.4 Future Research Issues and Challenges

Given its recent emergence and relative maturity as an important alternative approach for the provisioning and consumption of computing resources, there is relatively little published academic IS research on cloud computing to date. However, a review of the research papers included within the leading IS academic conferences in 2012 (e.g., the 2012 European Conference on IS, 2012 Pacific-Asia Conference on IS and the 2012 Americas Conference on IS) clearly shows that much research on cloud computing is in process. That said, it is also clear that many opportunities for comprehensive academic and applied research studies on the technological, business, and managerial opportunities and challenges associated with cloud computing remain. The levels of adoption of cloud computing motivate a need to reevaluate much of the prevailing wisdom about computing across almost every chapter in this volume. Critical areas for which new insights will be needed include application services development and deployment methods for cloud computing environments; models and approaches for effective data management within distributed cloud-based systems; global regulations for data protection and data discovery, and management practices for adhering to these; enterprise architecture in the context of cloud-based services; services versioning and pricing; collaboration and collective intelligence in massively online cloud computing contexts; security and data privacy management; effective governance practices for cloud computing; and management practices for realizing value from cloud computing. Other areas of great importance are the implications of cloud computing for internal IT units and their requisite skills and capabilities for a model of business computing in which the dominant traditional competencies of design, development, and operation will be overshadowed by competencies in services architecture, brokering, and integration and in which users can assume much greater independence and control over their computing needs.

48.5 Summary

Cloud computing has emerged to offer important capabilities for corporate computing. For small- and medium-sized enterprises, the affordability, scalability, and simplicity of deployment of cloud computing are driving rapid adoption. Within these small- and medium-sized businesses, cloud computing is becoming the dominant approach for providing infrastructure services, application functionality, and business process capabilities. Cloud computing is diminishing many of the barriers to "enterprise-class computing resources" that have been previously available only to large firms with extensive financial resources and comprehensive internal IT management capabilities, and thus leveling the field for all players in the digital economy.

For large enterprises, cloud computing is providing compelling features and capabilities that augment and extend the accumulated portfolio of IT infrastructure and applications. Cloud-based approaches have been especially valuable for supporting the incorporation of social media interfaces, social network applications, tablet and smart phone devices, computing-intensive “deep analytics,” and storage-intensive “big data” opportunities. For users, cloud computing has offered the opportunity to “untether” from desktops and embrace mobile computing devices with access to powerful on-demand applications and interactive information services.

Of great significance for the future of computing are the realities that almost all venture capital for software start-ups is being directed toward ventures that are embracing a cloud-based distribution model and that most established enterprise software companies are actively developing and executing a cloud strategy for their products. While some features of cloud computing are new, enabled by recent technology innovations, it also has to be realized that the emergence of cloud computing is entirely consistent with the evolving pattern of business computing and information systems provisioning that has been developing for the past 70 years. Fortunately, much of the knowledge about effective approaches for realizing value from computing that has been accumulated over this period is immediately applicable to cloud computing. However, consistent application of this knowledge to guide management practices remains a perennial challenge.

Enterprise Mobility

Carsten Sørensen
The London School of Economics and Political Science

49.1 Mobilizing Interaction

49.1.1 From Telegraph to Mobile

The past 150 years signify unprecedented development in the ways organizations organize distributed activities. The invention of scientific management at the end of the nineteenth century along with technological innovations such as the telegraph, filing cabinets, and printers suddenly made it possible to manage large-scale organizational activities distributed across continents much more efficiently and effectively (Yates, 1989). A variety of physical information management technologies played an increasingly critical role, but the birth of the business computer in post-war 1950s marked the beginning of an era of rapid acceleration in the importance of complex digital information management for business across all sectors (Caminer et al., 1998). During the next 30 years, mainframe computers formed the backbone of organizational information management. The 1980s gave birth to the networked personal computer allowing further distribution of computing power (Hinds and Kiesler, 2002). Fast forward to the present and we witness the pulverization of computing access with myriads of mobile phones, digital recording devices, contact-less sensors, etc. (Yoo, 2010). Portable, handheld, and embedded client technologies are interconnected through personal, local, and global digital networks. The combination of powerful client technologies connected through high-speed networks to a variety of cloud services provides a powerful digital infrastructure, the consequences of which we have yet to fully grasp (Tilson et al., 2010).

49.1.2 Predictions

We tend to be rather poor at understanding the technological development when it is right underneath our noses. Several prominent predictions of the impact of information technology turned out to be off the mark (Sørensen, 2011, p. 20ff). IBM's Chairman Thomas Watson famously remarked in 1943, "I think there is a world market for maybe five computers." Digital Equipment Corporation cofounder Ken Olsen stated in 1977, "there is no reason for any individual to have a computer in his home." Even Bill Gates's proposition in the late 1980s that "Microsoft was founded with a vision of a computer on every desk, and in every home" now seems to greatly undershoot a reality littered with computation. Xerox Lab's Mark Weiser came close when he in 1991 stated that "The most profound technologies are those that disappear. They weave themselves into the fabric of everyday life until they are indistinguishable from it" and thus defined the foundation for ubiquitous information technology. Harold S. Osborne already in 1954 famously predicted a device similar to a mobile phone with a unique ID given to each person at birth and following him or her until death.

49.1.3 Researching Mobile Information Technology Practices

A variety of research has been conducted into mobile information technology practices, and this section briefly classifies the research into the four categories of studies: (1) the mobile phone applied in a general social context, (2) broad ranges of mobile and ubiquitous information technologies used in a social context, (3) the mobile phone used to support work activities, and (4) broad ranges of mobile and ubiquitous information technologies used for the purpose of work. The last category is labeled "enterprise mobility" and is the focus of the remainder of the chapter. Before leaping onto this important subject, the following will briefly discuss all four categories of mobile information technology research.

49.1.3.1 Mobile Phone in Society

It is not strange that a significant research effort has been put into understanding the role of one single technology—the mobile phone—in society. There are currently billions of mobile phones in use across the globe, and the use of mobile phones crosses geographical, social, religious, and income barriers. This has led to a number of books and articles within the field engaged in the social study of mobile communications. While significant and important, it is essential to note that this research field is mainly interested in studying social phenomena and seems less interested in understanding technological diversity. Good examples of this line of research are Agar's (2003) account of the history of the mobile phone; Baron's (2008) work on the coevolution of technological practices and language; and a large body of work exploring the new communicative practices and changes on social rituals emerging from mobile phone use by researchers such as Ling (2004, 2008), Harper et al. (2005), Licoppe and Heurtin (2001), Licoppe and Smoreda (2006), Licoppe (2004), Fortunati (2002, 2005), and Katz and Aakhus (2002), to name a few. The general and widespread global diffusion of mobile phone communication has been explored by Castells et al. (2007) and Funk (2004). Some research has also explored regional characteristics, for example, in Japan (Ito et al., 2005), in the Asia-Pacific region (Rao and Mendoza, 2005; Pertierra, 2007; Hjorth, 2009), and in developing countries in general (Horst and Miller, 2006; Donner, 2008).

49.1.3.2 Mobile and Ubiquitous Information Technologies in Society

Despite the immense global success of the mobile phone, there are good reasons for studying technological properties in use more broadly beyond this one incarnation. Mobile and ubiquitous technologies are used in conjunction with the mobile phone, and the mobile phone is integrating a number of previously distinct technologies. This shapes everyday life by what Yoo (2010) characterizes as "experiential computing," which is the everyday experience with a range of technologies embedding computational abilities, such as mobile phones, iPods, digital cameras, GPS navigators, digital photo frames, smart toasters, intelligent ovens, in-car entertainment systems, etc. Relatively little research beyond specific

studies into the human–computer interaction aspects has been conducted within this area, which can be characterized as the social study of ubiquitous computing. Good example of such research is the work on design, intimacy, and environment as digital technologies disappear into everyday life by authors, such as Weiser (1991), Norman (1988, 1993, 1999), Dourish (2001), Mitchell (1995, 2003), and Mccullough (2004). Researchers have also studied changes in influence and power distribution as a result of mobile and ubiquitous technologies, for example, the consumer impact of radio frequency identification (RFID) technology (Albrecht and McIntyre, 2006) and wearable computing for citizen activism (Mann and Niedzviecki, 2002).

49.1.3.3 Mobile Phone at Work

There is a relatively small body of research specifically focused on the organizational use of the mobile phone at work, which is striking when considering the organizational proliferation of this technology. It is, however, often difficult to specifically isolate the mobile phone at work since it will often be an element in a larger portfolio of mobile and ubiquitous technologies now when the mobile phone is less associated with the isolated connectivity of voice calls and SMS messaging. The social study of the mobile phone at work has researched a diversity of issues, such as the role of the mobile phone in maintaining ongoing social contact while at work (Wajcman et al., 2008); the intensification of work (Bittman et al., 2009); work–life boundary maintenance (Golden and Geisler, 2007; Wajcman et al., 2008); and the organizational use of mobile e-mail (Mazmanian et al., 2006; Straus et al., 2010). Although not research based, Kellaway's (2005) amusing fictional account of mobile e-mail forms a highly informative image into contemporary organizational life with mobile e-mail.

49.1.3.4 Mobile and Ubiquitous Information Technologies at Work: Enterprise Mobility

The emergent organizational use of a range of diverse mobile and ubiquitous technologies led Lyytinen and Yoo (2002b) call for more research into this subject. This call has largely been ignored across the information systems field the passing decade (Sørensen, 2011). While a significant amount of research has explored how individual users in a social context use the mobile phone, there is little research exploring the organizational use of more complex portfolios of mobile and ubiquitous technologies (Sørensen, 2011). Some research, however, does explore the issue of enterprise mobility. Several edited collections broadly explore mobile and ubiquitous technologies at work and mobile working (Andriessen and Vartiainen, 2005; Sørensen et al., 2005; Basole, 2008; Hislop, 2008; Kourouthanassis and Giaglis, 2008). A range of books are aimed at practitioners engaged in implementing enterprise mobility within their organization, for example, Lattanzi et al. (2006), McGuire (2007), Darden (2009), Reid (2010), and Sathyan et al. (2012).

This chapter reports on such research into enterprise mobility. It focuses on the mobilization of interaction at work through the application of mobile and ubiquitous information technologies. The aim is to provide a conceptual map of the core challenges the mobilization of interaction pose to individuals, teams, and organizations. The chapter argues that the mobilization of interaction at work challenges existing arrangements and that the complex human–technology relationship must be more closely considered in order to understand how to manage unintended consequences.

49.1.4 Mobile Enterprise

Organizations have rapidly adopted a range of mobile and ubiquitous information technologies to support instant connectivity, to access corporate infrastructures, and for a range of other purposes. The first bulky mobile phones from the 1980s have been replaced with smartphones and tablets offering fast Internet access. Tiny microchips and associated sensor technologies can be used to track objects, vehicles, and people, using, for example, RFID, near-field communication (NFC), and the global positioning system (GPS). A great variety of portable and embedded devices beyond the ordinary mobile phone serve a range of purposes. These arrangements move far beyond establishing connectivity between

people or granting access to information services. The technology also serves a variety of purposes implemented through machine-to-machine (M2M) connections.

Organizations, of course, constantly consider how emerging information technology can offer new possibilities, but equally, some technologies become important because they represent solutions to existing problems. This two-way bind of problems and solutions interacting through a mesh of technological and organizational arrangements is as old as information technology itself (Yates, 1989). Since the birth of the mainframe, organizations have engaged in an increasingly complex arrangement of locally and globally distributed activities (Urry, 2003). This has made it possible to geographically shift activities depending on changing needs, available skills, and cost levels, for example, extensively separating the design and production of goods and services. Apple's iPhone is designed in California and manufactured in China with components gathered from further distant countries. Its applications are downloaded from globally distributed server farms and are globally sourced from hundreds of thousands of small and large programming outfits. After-sales support is located wherever is most appropriate for the time of the day or the nature of the customer inquiry.

49.2 Capabilities and Performances

In order to understand this development in general and the organizational consequences of mobile and ubiquitous information technologies in particular, it can be helpful simply to consider the organizational application of mobile and ubiquitous information technologies as the technology performances carried out in the meeting of technological capabilities (see Figure 49.1) and the requirements of organizational activities. The diversity of capabilities is illustrated in Figure 49.1, and Figure 49.2 subsequently illustrates the relationships between capabilities, work requirements, and technology performances.

49.2.1 Mobile Capabilities

Let us first consider six categories of capabilities, or affordances, specifically important for the understanding of the unique characteristics of mobile and ubiquitous technologies at work.

49.2.1.1 Connectivity

The technological development has since the era of the telegraph signaled a process of radically increased connectivity, from the first transatlantic telegraph cable in 1866, over Bell's telephone patent in 1878 leading to ubiquity of telephones and subsequently fax machines, to Martin Cooper's first call on a

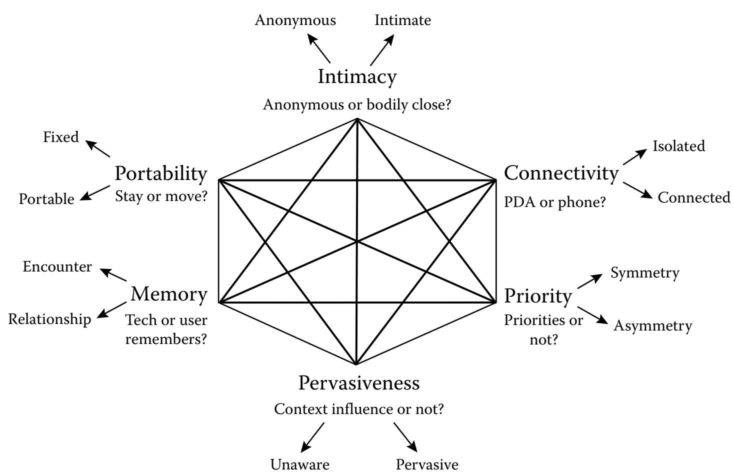

FIGURE 49.1 Overview of the six enterprise mobility capabilities.

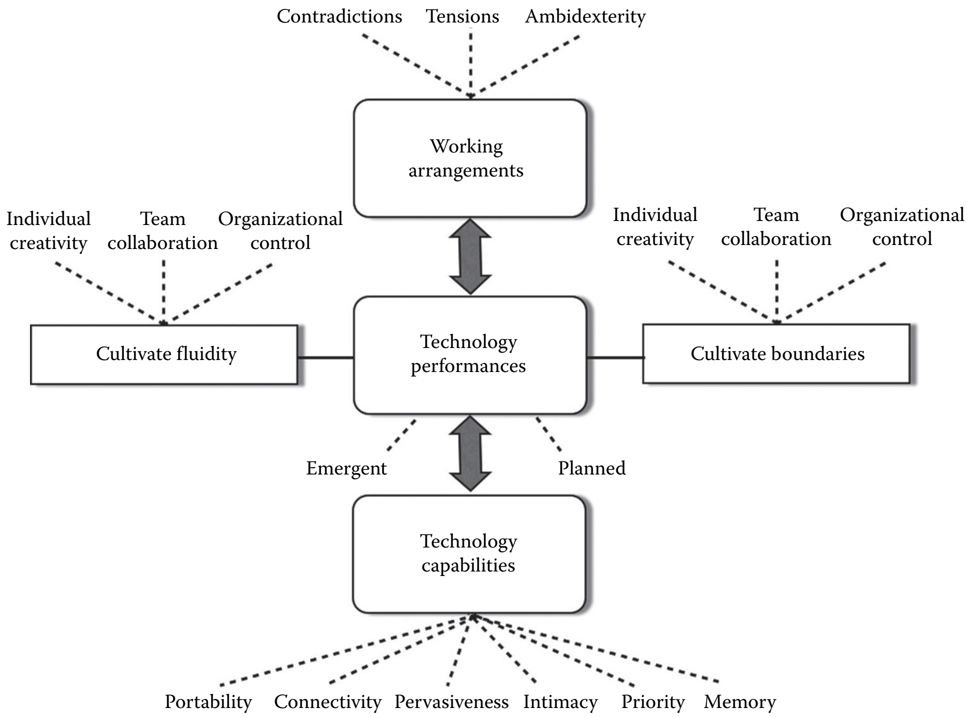

FIGURE 49.2 The cultivation of interactional fluidity and boundaries through emergent and planned technology performances when the contingencies of work meet technology capabilities.

handheld mobile phone in 1973 heralding the age of the mobile phone. Rapid development of cellular telecommunications networks followed from the first fully automated (1G) analog mobile network in Japan in 1979, over 2G networks from 1991, high data capacity (3G) networks from 2001, and to the emerging 4G networks. All of this has led to cheap global connectivity where in 2003 mobile phone subscriptions first exceeded fixed-line subscriptions. The year 2012 saw more mobile-connected devices than people on Earth, and it is estimated that 16 billion mobile devices will be interconnected in 2016 (Cisco, 2012).

49.2.1.2 Portability

The miniaturization of information technology has, during the past decades, produced increasingly portable, yet powerful, computational devices. This portability of the computing device forges closer relationships between the technology and the geographical movement of users, objects, and vehicles. Computation is not restricted to specific locations, but can follow organizational processes and members. The term "mobile technology" most frequently refers to the combination of a portable client connected to a network, for example, the mobile phone used for calls and SMS messages. However, in the context of this chapter, mobile technology in a much broader sense refers to technologies that can combine any of the six types of capabilities listed in Figure 49.1: portability, connectivity, intimacy, pervasiveness, memory, and priority.

49.2.1.3 Intimacy

One of the key assumptions is that the closer a technology is situated to the human body, the more critical the user–technology relationship becomes. The mainframe may be important, but the personal computer is highly personal, yet not as critical as the mobile phone, which takes up a position on par with keys and credit cards (Chipchase et al., 2004). The user may consider mobile and ubiquitous technologies as intimate

since it is bodily close and continuously follow the user. However, in terms of technological capabilities, intimacy is in this chapter denoting the ability of the technology to explicitly support an intimate user relationship, for example, by recording user behavior and modeling user preferences. If the technology continuously records and models user behavior and preferences, it can directly support the forging of intimacy.

Capabilities rendering the user known through monitoring, modeling, and interaction signify technologized intimacy, for example, the close proximity to the human body of the client parts of the technology and the ongoing technology relationship fostered by the user. When combined with connectivity, the intimacy can relate to the identifiability of the user through the close physical proximity with technology.

49.2.1.4 Pervasiveness

Pervasiveness here signifies a computer's capability of relating directly to its environment (Lyytinen and Yoo, 2002a). A pervasive washing machine sensor can allow for the control of soap according to how dirty the water is. A GPS navigator keeps track of a vehicle's location through awareness of its location in relation to geostationary satellites. The much-used term "ubiquitous computing" is then defined as the combination of portability and pervasiveness with the combined ability to both sense the environment and be carried through it (Lyytinen and Yoo, 2002a).

49.2.1.5 Memory

The technological capability of remembering supports a fundamental distinction between technology merely treating the user relationship as separate and unrelated encounters, as opposed to technological capabilities enabling user interaction forming an ongoing relationship in which the technology can record activities and subsequently react upon these. When the technology does not support memory of an ongoing process, the user is solely responsible for constructing and maintaining memory of the process. When the technology explicitly maintains memory of aspects of the process, the technology can support by managing aspects of the process complexity (Carstensen and Sørensen, 1996). Technology-based memory is generally a prerequisite for comprehensive support of complex decision processes (Mathiassen and Sørensen, 2008).

49.2.1.6 Priority

In a similar manner to information technology supporting the remembering aspects of the interaction, it can also support the prioritization of interaction. While the user of course continually engages in assessments and prioritization when, for example, looking at a phone when called, some of the prioritization can also be supported explicitly by the technology. This can be implemented in the form of a variety of notification and filtering capabilities supporting rules stipulating how the interaction should unfold or directly supporting human choices through providing additional information about the interaction. Such prioritization explicitly treats the interaction as asymmetrical, whereas an absence of priorities implies the assumption of interaction symmetry. Mobile and ubiquitous technologies can directly support the prioritization of interaction through various filtering and awareness mechanisms, for example, by directly excluding or including specific interaction depending on information about content, caller identity, etc. (Oard, 1997; Ljungberg, 1999; Sørensen, 2010). The technological capability of supporting interaction prioritization relates directly to research into user awareness (Heath and Luff, 2000), interruptions (McFarlane, 1998; Rennecker and Godwin, 2005; Wiberg and Whittaker, 2005), and information overload (Hiltz and Turoff, 1985; Schultze and Vandenbosch, 1998; Eppler and Mengis, 2004; Iastrebova, 2006; Harper, 2010).

49.2.2 Complexity of Technology Performances

Enterprise mobility is, in short, the organizational application of complex combinations of the six capabilities discussed earlier embedded in mobile and ubiquitous information technologies. This application

is governed by the emerging characteristics of the work situations the users find themselves in (see Figure 49.2). These situations are often conflicting and contradictory, and therefore calling for a combination of planned and emerging usage of the technology (Sørensen, 2011). Some activities are characterized by a very high degree of individual discretion regarding what needs to be done and how precisely this must be accomplished. Other activities are governed by next to no rules and procedures and thereby requiring extensive discretion on the part of the individual. A majority of activities share characteristics from both and will require some discretion and therefore also require both planned and emergent technology performances.

The complexity emerging when specific combinations of mobile information technology capabilities within a specific portfolio are evoked cannot easily be characterized in terms of straightforward linear causality between the aim of the activity and an associated performance. Rather, the negotiations of contradicting requirements emerging from the situation can lead to the user engaging different actions with the technology depending on the specific situation, the mood of the user, and a range of other aspects. As an example, the decision by an individual of whether or not to answer a call on their mobile phone is not necessarily straightforward and will depend on a range of factors, for example, who the caller is (if this can be ascertained a priori), what the recipient is currently doing, or what he or she guesses the caller wishes to discuss. A straightforward mapping can only be made between a set of technology performances by the user against a discrete set of situations if any possible individual discretion has been removed from the work conducted. Emerging aspects of work will in most cases make it necessary for the user to engage in emerging technology performances taking the specific situation into consideration (Sørensen, 2011).

49.3 Cultivating Fluidity and Boundaries at Work

The organizational impact of mobile and ubiquitous information technologies is difficult to document precisely given that the technology is applied in a great variety of roles, spanning work with very little individual discretion to work relying on extensive individual discretion. Within field force automation, it may be complicated, yet doable, to assess the benefits of increased use of mobile and ubiquitous information technologies as the work process can be codified and measured against a computer-calculated ideal process. The technology performances will in this case be treated similarly to the steps in an automated manufacturing process where the components are expected to behave in a certain manner at a certain point in time.

At the other end of the discretion spectrum, top executives or highly independent professionals are expected to largely govern their own activities and make choices they deem appropriate according to the specific situation. For this type of work, it can be almost impossible to devise simple measures for process quality, and simply measuring the outcome does relatively little to factor out the importance of particular technology performances. However, most work will be characterized by being governed by some organizational rules, while retaining some degree of discretion. Furthermore, it is often far from trivial from a distance to ascertain to what extent work can be conducted without discretionary decisions as unanticipated exceptions can call for emerging technology performances.

49.3.1 Anytime/Anywhere or Sometime/Somewhere?

The ability to engage in mobile technology performances anytime, anywhere, and with anyone is an often-cited practical implication of the application of mobile and ubiquitous information technologies. While this can technically be correct, such focus emphasizes the technological opportunities in Figure 49.2 over the organizational opportunities and constraints. While a mobile phone allows for interaction with virtually anyone on Earth, this does not reflect any organizational reality. Work is always situated in some context where certain issues, people, contexts, and time slots have more importance over others. Possessing a colleague's mobile phone number does not necessarily mean that the person can be called

at any time. When combining the technological opportunities with the organizational realities, the technology performances are conducted as complex arrangements where interaction occurs sometimes, somewhere, and with someone (Wiberg and Ljungberg, 2001). The everyday mobile technology performances are ones hovering between being anytime and the sometime, and for the participants, this is in itself often a subject of negotiation.

49.3.2 Distance and Movement Matter

Olson and Olson (2000) argue that despite serious attempts to completely alleviate the importance of distance in collaboration, distance still matters. Collaboration across distances imposes a separate set of issues that must be overcome, even if the technology at the same time does facilitate highly distributed work (Olson and Olson, 2000; Dubé and Robey, 2009). In the use of networked personal computers, distance both matters as a barrier for interpersonal collaboration and, at the same time, matters as it also directly facilitates remote collaboration.

It can similarly be argued that the use of both mobile and ubiquitous technologies suddenly makes the physical location of the user more important than before—movement matters when mobile and ubiquitous technologies are deployed in an organization (Sørensen et al., 2012). The technology performances will frequently relate to human movement and therefore create a whole new set of issues related directly to the negotiation of interaction in movement. We can hardly assume that this does not create new challenges for the participants—especially if the movement cannot be made the subject of collective inquiry. The opening questions of "Where are you?" and "Did I disturb?" directly relate to matters of distance and movement.

However, for the organization, movement also matters when mobile technology helps loosen constraints for its members' locations and movements. When organizational members by circumstances are forced to work at their workstation, their movement is mostly a matter of ensuring sufficient number of working hours and to arrange around this constraint. When they are able to work from a range of locations while moving, their location and movement are no longer merely issues of personal preference. They become important operational, tactical, and even strategic concerns. Sales organizations with traveling salespeople have of course known this for a long time. However, mobile technology performances make it possible to engage in more fine-grained decisions regarding the distribution of work across time and location.

In the traditional workplace, roles could relatively easily be identifying those that required other arrangements that stationary working with no movement and being colocated with everyone else in a fixed office or by a machine (see Figure 49.3). In the mobile enterprise, roles are open for more flexible assignments. Some work may at times need to be organized as locally mobile within a specific location. At other times, work may require as arranged as remotely distributed from other colleagues, yet fixed at a desk. Yet at other times, work may need to be organized as mobile working, i.e., both remotely located and mobile.

49.3.3 Balancing Fluidity and Boundaries

As discussed earlier, mobile technology performances represent choices regarding the unfolding of activities and interactions across time and locations. With the networked personal computer, distance took on new meanings, and with mobile information technology, so does movement. The performances are localized individual or collective judgments regarding the combination of technological possibilities when faced with a possibly contradicting organizational reality. The performances can in these situations result in the removing of existing boundaries for interaction—establishing more fluid interaction. The use of mobile e-mail is a good example to the extent that members of the organization choose to use e-mail as a horizontal means of communication transcending previous lines of reporting and responsibility. However, mobile technology performances can also establish new or reinforce

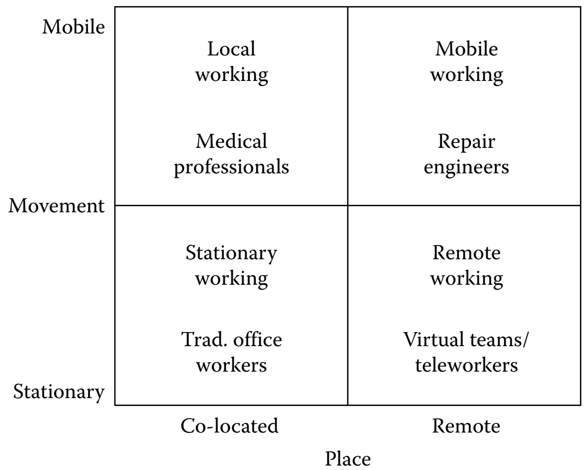

FIGURE 49.3 Separating remote distribution and movement, four analytical categories of working emerge: stationary, remote, local, and mobile working. (Adapted from Sørensen, C. *Enterprise Mobility: Tiny technology with global impact on work*. Technology, Work and Globalization Series, 2011.)

existing boundaries for interaction (see Figure 49.2). Not only can mobile performances set people free from their desks so they can move where it makes most sense to them, to the teams they work in, or to the organization as a whole. The performances can also bring organizational routines, procedures, and infrastructure along and through intimacy and pervasiveness support that specific procedures are enforced or that certain lines of command obeyed. It is, in other words, not a simple matter to ascertain what outcomes mobile performances can entail as mobile technology performances contain the inherent duality of both contributing to increased fluidity and boundaries in decision processes.

The following discusses the cultivation of fluidity and boundaries through mobile performances at three different levels of analysis: (1) individuals creatively seeking fluid performances by balancing availability and engaging boundaries for interaction, such as turning off the phone; (2) teams seeking to engage in transparent collaboration by balancing fluid internal team interaction with boundaries for how they interact with others outside the team; and (3) organizations seeking to cultivate interactional boundaries within the organization and at its boundaries.

49.3.3.1 Individual Creativity

The performance can support individuals in engaging in fluid working practices with few boundaries hindering interaction if this is deemed suitable and with the individual cultivation of barriers for interaction when needed, for example, through filters blocking out requests. The extensive use of mobile information technology over years renders the individual a highly experienced professional in engaging in such cultivation, within the technological constraints. For example, usage throughout a 40 h working week will within 5 years have accumulated the 10,000 h of practice cited as necessary for true expertise within a domain (Simon and Chase, 1973; Ericsson et al., 1993; Gladwell, 2008; Sørensen, 2011). We have found a number of very good examples of such expertise in creative cultivation of mobile performances in our studies (Sørensen, 2011, pp. 77–100).

The Japanese CEO, Hiro, for example, engages in highly complex performances when moving freely around Tokyo to get inspiration for new mobile services his small company possibly could build and launch (Kakihara and Sørensen, 2004). Hiro conducts "innovation by walking around" and extensively relies on advanced filtering features implemented on his mobile phone. This results in a number of profiles emitting different noises depending on the caller or the mobile e-mail sender. He prefers most interaction to be channeled to mobile e-mail so he can quickly scan the requests and prioritize which ones he acts upon when. This transforms synchronous and asynchronous interaction into the asynchronous

e-mail, which allows Hiro to constantly filter and monitor incoming interaction. In this way, immediate requests can be prioritized before acted upon, and Hiro also argues that he in reality in this way uses the asynchronous mobile e-mail as an almost synchronous technology as he constantly checks e-mails. The arrangement, however, provides him with a slight buffer allowing instant prioritization—a task more difficult with truly synchronous interaction. He also relies significantly on a stationary administrator as a means of managing his availability and interaction requests.

The London black cab driver Ray also engages extensively in the cultivation of fluid interaction (Elaluf-Calderwood and Sørensen, 2008). His extensive training and experience in navigating the streets of Central London without other navigational support than his memory allows him to define his own rhythm of working. He can independently choose where he places the cab in order to maximize his income, and as such he is a stationary, yet mobile, example of the direct importance of discretionary choices concerning location and movement. He receives some jobs from colleagues via mobile phone when a sudden demand appears and others centrally dispatched from a computer cab system. However, most jobs appear when customers in the street hail his cab or when he is at the front of a taxi rank.

For the Middle Eastern foreign exchange trader, Khalid, the day job consists of office-based trading, but outside normal working hours, he engages in mobile trading using a mobile phone and a specialized mobile device providing market information (Sørensen and Al-Taitoon, 2008). Here, the balancing of home and working life is a major aspect of the balancing of fluidity and boundaries.

Common for these three examples is the extensive reliance on movement as a means of doing the work. For the CEO and the cab driver, the movement is in effect an integral part of the work, whereas for the trader, movement is an essential aspect of striking some balance between work and family requirements. When engaged in mobile working, all three are largely either independent or largely able to shape their own work. They can over time cultivate a sense of rhythms of working and of interaction supporting the cultivation of fluid working and the management of interruptions (Sørensen and Pica, 2005; Sørensen, 2011, pp. 94–100).

49.3.3.2 Team Collaboration

For teams engaged in collaboration and in the coordination of mutual interdependencies, the ability to obtain fluid and transparent negotiation of these interdependencies is a key concern. It is obviously both pregnant with opportunities and fraught with problems to obtain such fluidity when team members are both scattered and moving rather than when everyone is situated within the same office space.

For the police officers John and Mary, their interaction is largely conducted within their patrol vehicle, where they have continuous contact with the control room through an in-car terminal and radio system (Sørensen and Pica, 2005). When out of the vehicle and engaged in an incident, they rely heavily on the flexible means of a shoulder-mounted radio as a constant connection to the control room and to each other. The in-car system represents complex interaction boundaries between teams as it streamlines the coordination of officers accepting to attend incidents. The team of two officers constantly cultivates the rhythms of working both establishing fluid activities and cultivating interactional boundaries. In doing so, they rely extensively on a wide range of the technological capabilities discussed previously.

For Simon, a security guard doing rounds on industrial estates in Manchester, the coordination of work with the control room consists of little individual discretion (Kietzmann, 2008). His activities are almost automatically directed by a system whereby he swipes a RFID-reader mobile phone over an embedded RFID chip and the system informs him via SMS where to go next. Collaboration is here entirely codified through a specific set of stipulated performances.

One of the important aspects of managing the negotiation of mutual interdependencies is formed by decisions regarding interaction priority. If all interaction is prioritized equally, then the associated interactional symmetry will rely on the individual member to manually prioritize interaction. In both the cases mentioned earlier, systems embed capabilities supporting prioritization of interaction to facilitate more effective collaboration. Mobile technology performances also challenge traditional notions of individual versus collective working as the extensive use of mobile interaction can

support the individualization of highly interdependent activities (Barley and Kunda, 2004; Felstead et al., 2005; Sørensen, 2011).

49.3.3.3 Organizational Control

From the perspective chosen here, an organization can be viewed as a specific arrangement of boundaries for interaction and facilitators for fluid interaction. Organizations will, from this perspective, spend considerable effort cultivating internal boundaries so they facilitate desirable fluid interaction and limit undesirable interaction. Similarly, much effort will be invested in cultivating the organizational boundary enabling some and hindering other forms of interaction.

For the restaurant supply delivery driver Jason, work is regularly challenging organizational arrangements (Boateng, 2010). When delivering goods to a restaurant he has, against procedure, provided the owners with his private mobile phone number instead of forcing customers to contact the call center who thereafter would contact Jason. He will also, for practical purposes, at times neglect procedures of not waiting in case a customer is not present at the restaurant. Such arrangements are obviously both efficient and desirable from Jason's perspective, yet ineffective from an organizational perspective. If and when Jason leaves his job, customers will be frustrated as they no longer can use the established fluid arrangement of just calling Jason's mobile. Also circumventing the call center results in order discrepancies not always being properly logged within the system. However, in the tension between centrally fixed boundaries and Jason's circumvention of these boundaries, Jason manages to carve out a little extra discretion for himself.

The hospital nurse Yin, who is further educating herself to a new role along with 15 other colleagues within the British Health Service, is caught up in a clash of arrangements of organizational fluidity and boundaries between the local hospital where she spends most of her time and the central London-based organization responsible for her further education, which she attends 1 week in 6 (Wiredu and Sørensen, 2006). Conflicting local and remote requirements cannot be reconsolidated through the use of mobile technology performances. The remote organization desires intense documentation of the remote work-integrated learning process. The local hospital does not see the importance of this documentation and establishes strict boundaries for interaction, for example, by not allowing her to use mobile technology in normal working hours. The end result is that the technology performances are abandoned for documentation purposes, and the London-based learning team instead relies on Yin's movement to resolve the issue. Every 6 weeks for a year, she attends 1 week sessions in London, and these sessions are deemed sufficient as means of documenting her learning. In this example, the organizational constraints and boundaries lead to human movement directly replacing mobile technology performances.

Table 49.1 summarizes the enterprise mobility capabilities discussed earlier and illustrates the diversity of capabilities across cases.

49.3.4 Enterprise Mobility and Organizational Complexity

Mobile technology performances can serve organizational purposes by providing both direct remote observation and indirect remote control. Such attempts can at the same time be subjected to a variety of counteractivities to serve individual or team purposes. For the organization, mobile technology performances represent both new opportunities for reengineering of traditional boundaries in order to obtain more effective decision flows and challenges as ineffective boundaries can lead to suboptimal interactional boundaries and much misdirected or wasted effort. For the Middle Eastern bank engaging in mobile foreign exchange trading after normal working hours, mobile technology performances represent the only viable solution to the problem that the bank wished to engage in 24 h trading without maintaining a trading floor around the clock. The solution of shifting trading across the globe following the sun was not feasible. Neither was home-based trading fixing traders by their personal computer all evening and night. However, although mobile trading clearly resulted in stress on the traders home life/work life balance, it at least represented a solution acceptable to both the bank and the traders.

TABLE 49.1 Illustration of the Diversity of Capabilities across the Example Cases Discussed in Section 49.3.3.3

			Enterprise Mobility Capability					
Name	Job	Technology	Portability	Connectivity	Intimacy	Pervasiveness	Memory	Priority
Hiro	CEO	Mobile phone	Yes	Yes	Yes	No	Yes	Yes
Ray	Cabbie	Computer cab system	No	Yes	Yes	Some	No	Some
Ray	Cabbie	Mobile phone	Yes	Yes	No	No	No	No
Khalid	Trader	Terminal	Yes	Yes	Yes	No	Yes	Yes
John and Mary	Police	Mobile data terminal	No	Yes	Yes	No	Yes	Yes
John and Mary	Police	Personal radio	Yes	Yes	No	No	No	No
Simon	Security	RFID phone	Yes	Yes	Yes	Yes	Yes	Yes
Jason	Driver	Mobile phone	Yes	Yes	No	No	No	No
Yin	Nurse	Handheld assistant	Yes	No	No	No	No	No

Establishing much tighter and more interactive connections between individual workers and portable technology connected to communication networks allows for the contradicting purposes of both (1) tightening centralized control and codification of the work process and (2) providing increased decentralization and individual discretion through extensive access to the necessary corporate information. This development resembles the distinction between the use of information technology for either codifying or informating work discussed in the 1970s and 1980s when information technology was introduced in a range of sectors (Zuboff, 1988). However, this time it is personal as the technology is not an organizational anonymous entity but linked directly to individuals. The role of enterprise mobility and mobile technology performances can be viewed as one means of supporting organizational paradoxes.

Organizations experience the difficulties of balancing a variety of concerns, for example, balancing long-term exploration of opportunities with short-term exploitation of current abilities, being flexible and agile while securing stable structures for decision making, or balancing concerns for internal and external focus (Quinn and Rohrbaugh, 1983; Birkinshaw and Gibson, 2004; O'Reilly III and Tushman, 2004). The ability of an organization to be ambidextrous has been forwarded as a solution to managing organizational paradoxes where the organization needs to follow two seemingly contradicting logics. However, it has been argued that altering structural arrangements is not a long-term solution to this problem. Instead, the balancing of contradicting concerns must be delegated to individuals in the organization who then can make discretionary decisions depending on the actual situation and thereby enable contextual ambidexterity (Birkinshaw and Gibson, 2004). Enterprise mobility can serve as one of the means supporting organizations in achieving such contextual ambidexterity since it can ensure a much more consistent and comprehensive individual access to both the necessary information, access to the appropriate colleagues, while simultaneously support the detailed implementation of organizational procedures and control arrangements (Sørensen, 2011, pp. 49–52, pp. 158–167).

49.4 Enterprise Mobility Research Challenges

The research field studying enterprise mobility is still in its relative infancy despite the practical importance of the technology in many organizations. As an illustrative example, despite a prominent call for action to researchers in 2002 for the information systems field to investigate the organizational use of

mobile and ubiquitous information technologies (Lyytinen and Yoo, 2002b), a decade later, only less than 4% of all papers in the top-eight journals even remotely explored the subject (Sørensen, 2011, p. 9).

49.4.1 Individual Intimacy and Organizational Trust

One of the primary challenges of understanding both opportunities and challenges in the organizational use of mobile and ubiquitous information technologies relates directly to the increased intimacy and pervasiveness offered by the technological capabilities. The technology affords intense investigation into individual micropatterns of behavior, thus making highly intimate aspects of everyday working life susceptible to intense scrutiny. It also affords the close and intimate connectivity between the work environment and technological properties, enabling the codification, mapping, monitoring, and calculation at an immense scale. Google's effort to map street views led to significant debate over privacy when the passing Google car has caught people on the images, but the combination of intimacy and pervasiveness will require a significant shift in our understanding of the complex relationships between technological opportunities and prevailing opinions of individual privacy. The success of advanced enterprise mobility capabilities will rely even more critically on interpersonal and organizational trust than other technological innovations in the enterprise, precisely because enterprise mobility connects technology and person even tighter than previous information technologies. The workers could quite literally end up having everywhere to go and nowhere to hide.

49.4.2 Optimizing Knowledge Supply Chains

From a broader organizational perspective of understanding the bigger picture, one of the significant challenges is to understand how to more flexibly manage the opportunities of fluidity and boundaries. Considering the advantages gained by computerizing the manufacturing supply chain, enterprise mobility represents the challenge of understanding how computerization of the knowledge or service supply chain through mobile information technology can lead to advances. However, while the nuts and bolts of highly distributed manufacturing processes do not care much about what is written about them in various databases, humans very much do. One of the challenges in this is to understand the balancing of individual privacy concerns with the organizational advantages of large-scale real-time big-data analysis. As technology and its application advance, increasing amounts of highly detailed data are collected concerning organizational and interorganizational processes and their outcomes (Benkler, 2006; Kallinikos, 2006; Ayres, 2007; The Economist, 2010). Such data represent the opportunity for the organization to flexibly define its internal and external behavior depending on the emerging contingencies and thereby achieve contextual ambidexterity. For individuals, teams, and organizations, the challenge is to understand how to flexibly configure portfolios of technological capabilities to support the balancing of interactional fluidity and boundaries as this increasingly is up for negotiation and not predetermined by the physical arrangement of workstations, offices, and buildings.

49.4.3 Rapid Technological Developments

It is a key concern to explain how enterprise mobility is not only similar to but also differs from other organizational technologies. It is clearly feasible to look at traditional implementation and work effectiveness issues with this particular technological intervention as with other technologies. However, the key challenge is to identify issues of particular importance for mobile and ubiquitous information technologies. As an example, the closer relationship and instant feedback loops between the user and the technology can perhaps create new types of dependencies (Mazmanian et al., 2005). Unpacking how the constantly changing technological opportunities and ongoing changes in working practices interrelate is a core concern and must relate directly to a theoretical understanding of essential changes in technological opportunities. As an example, the recent development of mobile smartphone and tablet application stores has significantly

shifted the opportunities for organizations to more easily deploy complex mobile technology using worker self-service and relying on consumerized solutions. The unpacking of how rapidly changing technological circumstances and changing organizational practices interrelate is a complex endeavor but necessary for the further understanding of enterprise mobility. The aforementioned cases illustrate complex use of a variety of the technological capabilities presented in Figure 49.1: portability, connectivity, intimacy, pervasiveness, memory, and priority. The mere fact that the technology reaches widely from the user's hand over the built environment to global infrastructures makes the dynamics even further complex.

49.4.4 Paradoxical Technology Relationships

Much research of socio-technical phenomena tends to adopt the assumption that the user–technology relationships are straightforward, stable, and predictable. However, this is a questionable assumption, especially when the technology in question assumes a highly intimate relationship with the user (Arnold, 2003). For enterprise mobility, the user–technology relationship is highly interactive and relies on close physical proximity and constant connectivity, and the performance relating a user's goal and a specific technical capability cannot be described as linear and simple. Assuming that the user is bestowed some degree of individual discretion, the technology will often allow the same operation to be conducted applying different technology performances by selecting from a portfolio of opportunities. Furthermore, situational richness will likely imply that the user is not able to act as simply mapping discrete goals and technological opportunities. Rather, a range of concerns may concurrently compete as triggers of specific intent. When a person receives a mobile e-mail, the decisions regarding what to do will be informed by a range of situational factors. Also the outcome itself of the technology performances can influence future situations. The constant checking of mobile e-mail and instant replies also creates the need to further check and manage the environmental expectations of continuing to constantly reply to e-mails. This signals paradoxical technology relationships where the technology concurrently both fulfills and creates needs; simultaneously is public and private; supports mobility, yet enables a constantly fixed point of contact; and bestows the user with competence, yet also renders the user incompetent (Mick and Fournier, 1998; Jarvenpaa and Lang, 2005). While other technological innovations may also display such characteristics, mobile and ubiquitous information technologies will further challenge the notion of simple linear relationships between situations, technological capabilities, and technology performances. Research into mobile and ubiquitous technologies must seek to identify and explain the specific socio-technical complexities emerging when the technology is adapted and shaped by individuals, teams, and organizations. This chapter has sought to identify some of the unique aspects, for example, in terms of the importance of human movement. The chapter has also explored the organizational use of mobile and ubiquitous technologies beyond a simple logic of straightforward relationships between what the technology can offer and how it is used. This relates directly to the emerging notion of complex relationships between user behavior and available portfolios of organizational information services (Mathiassen and Sørensen, 2008). A promising research approach can be the detailed mapping of micro-coordination practices (Ling, 2004; Licoppe, 2010) using novel techniques seeking to uncover hidden patterns in complex nonlinear phenomena (Gaskin et al., 2010, www.orgdna.net).

49.5 Summary

Enterprise mobility—the organizational application of mobile and ubiquitous information technologies is a significant, yet underresearched, area of computing. This is despite a significant practical relevance of the subject. The challenges for practitioners and academics alike are to understand the specific opportunities and challenges imposed by this technological development and the associated organizational practices. This chapter has argued that the core challenges relate directly to the ability of the technology to intimately relate to and interact with the user, to manage, prioritize, and remember ongoing interaction processes with the immediate environment, while connecting through personal, local, and global communication networks. It is argued that these capabilities in nonlinear ways relate to user goals through

planned and emergent technology performances. Such novel technology performances, it is argued, can intentionally or unintentionally challenge existing interactional boundaries at the individual, team, and organizational level. For the individual, mobile technology performances can both facilitate new interactional practices and require the creative management of these opportunities to establish fluid working. For the team, the effective and transparent negotiation of highly distributed interdependencies also requires careful balancing of instant fluid access with boundaries for interaction. At the organizational level, fluid decision processes must be balanced with the cultivation of internal and external interactional boundaries. The introduction of mobile and ubiquitous technologies can mark a way of rendering (1) the individual more available while in charge of his or her own work; (2) teams more effective; and (3) organizations more flexible, yet better controlled. Such arrangements can be viewed as incremental changes to existing arrangements. However, the significant potential of enterprise mobility is of course to allow for new business models and disruptive organizational arrangements, for example, challenging assumptions about organizational membership and individual flexibility at work (Barley and Kunda, 2004).

Typically, an unintentional effect is increased interactional fluidity where individuals suddenly are given opportunities for more flexible and fluid access to information resources or colleagues. This can in turn result in both increased effectiveness if it allows for more meaningful connections, and also, as the examples demonstrate, tensions between individual and organizational concerns. It is, therefore, essential that individuals, teams, and organizations constantly cultivate the balance between technology performances increasing fluid organizational arrangements with those establishing interactional boundaries. Such efforts require significant improvements in our understanding of the complex and paradoxical relationships between the constantly developing diversity of technological capabilities and changing organizational practices.

Glossary

1G: First-generation analog cellular telecommunications networks
2G: Second-generation cellular telecommunications networks, which were digital
3G: Third-generation cellular telecommunications networks offering increased data transmission rates
4G: Fourth-generation cellular telecommunications networks with even faster data transmission rates
Cellular telecommunications network: Radio network that uses the geographical partitioning into cells as a means of reusing frequency bands
GPS: Global positioning system
M2M: Machine-to-machine
NFC: Near-field communication
RFID: Radio-frequency identification

Sustainable IT

Edward Curry
National University of Ireland Galway

Brian Donnellan
National University of Ireland Maynooth

50.1 Introduction

Sustainable IT is the design, production, operation, and disposal of IT and IT-enabled products and services in a manner that is not harmful and may be positively beneficial to the environment during the course of its whole-of-life [1]. Sustainable IT requires the responsible management of resources (both IT and non-IT) encompassing environmental, economic, and social dimensions. The first wave of sustainable IT, *Greening of IT,* aims to reduce the 2% of global greenhouse gas (GHG) emissions for which information technology (IT) is responsible [2], by reducing the footprint of IT thought actions such as improving the energy efficiency of hardware (processors and disk drives) and reducing waste from obsolete hardware. The second wave of sustainable IT, *Greening by IT,* also called Green IT 2.0 [3], is shifting the focus toward reducing the remaining 98%, as illustrated in Figure 50.1, by focusing on the innovative use of IT in business processes to deliver positive sustainability benefits beyond the direct footprint of IT, such as monitoring a firm's emissions and waste to manage them more efficiently. The potential of *Greening by IT* to reduce GHG emissions has been estimated at approximately 7.8 Gt CO_2 of savings in 2020, representing a 15% emission cut in 2020 and 600 billion ($946.5 billion) of cost savings [2]. It is estimated that the use of IT for greening will play a key role in the delivery of benefits that can alleviate at least five times the GHG footprint of IT itself [4].

This chapter provides an overview of sustainable IT best practices followed by discussion of the challenges faced by IT organizations in delivering sustainable IT. Green for IT practices covered include how software should be designed to minimize its resource usage, how the energy efficiency of data centers (DCs) can be improved through the use of virtualization, air management, and cooling, and the life cycle assessment (LCA) process that is used to determine the environmental impact of a

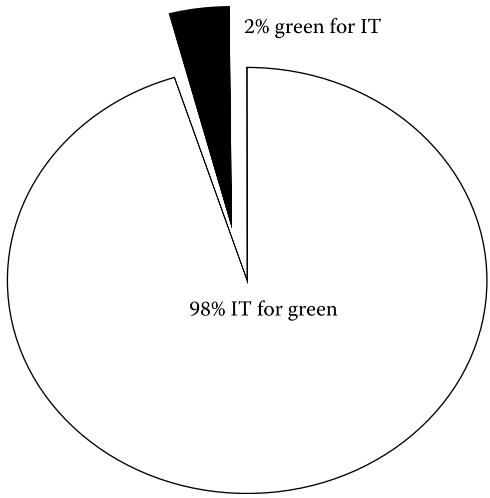

FIGURE 50.1 Target potential CO_2 reductions for sustainable IT.

product or service. Practices for IT for Green include how energy can be effectively managed with Green Information Systems (IS). Next, the chapter examines the challenges facing IT organizations as they put sustainable IT best practices into action, including how to benchmark the maturity of the sustainable IT. The chapter finishes with a brief look at future sustainable IT research directions and with a summary.

50.2 Two Faces of Sustainable IT

Sustainable IT is a broad topic that can have many motivations including:

- Self-interest (image, competitive advantage, innovation)
- Social, cultural, and political influence
- Regulatory and compliance requirements
- Environmental concerns
- Economic benefit

There are substantial inefficiencies in IT and its usage behavior that can be readily addressed. As illustrated in Figure 50.2, there are two faces to sustainable IT: Green for IT and IT for Green.

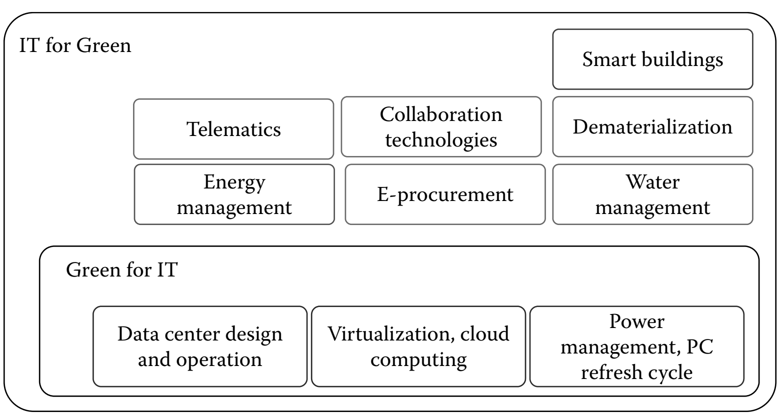

FIGURE 50.2 Two faces of sustainable IT.

50.2.1 Green for IT

Murugesan [5] details a holistic approach to *Green for IT* that comprehensively and effectively addresses the environmental impacts of IT using four key practices:

- *Green use of IT systems*: Reduce the energy consumption of computers and information systems and use them in an environmentally sound manner.
- *Green disposal of IT systems*: Refurbish and reuse old computers and properly recycle unwanted computers and other electronic equipment.
- *Green design of IT systems*: Design energy-efficient and environmentally sound components, computers, servers, and cooling equipment.
- *Green manufacturing of IT systems*: Manufacture electronic components, computers, and other associated subsystems with minimal or no impact on the environment.

By following these four practices, the environmental impacts of IT can be reduced to improve its sustainability throughout its entire life cycle. Examples of Green for IT include:

- Energy-efficient DC design and operation
- Virtualization and cloud computing
- Power management
- PC-refresh cycle
- Energy-efficient computing
- Responsible disposal and recycling of IT equipment
- Eco-labeling of IT products

50.2.2 IT for Green

There is substantial potential for sustainable IT to bring together business processes, resource planning, direct and indirect activities, and extended supply chains to effect positive changes across the entire activities of governments, organizations, and individuals. *IT for Green* is concerned with analyzing, designing, and implementing systems to deliver positive sustainability benefits beyond the direct footprint of IT, such as monitoring a firm's emissions and waste to manage them more efficiently. IT for Green provides an opportunity for the innovative use of IT in business processes to improve resource management. Examples of IT for Green are:

- Smart buildings
- Energy management
- E-procurement
- E-waste
- Telematics
- Water management
- Collaboration technologies
- Dematerialization

Understanding how to utilize sustainable IT requires understanding how IT can be used to improve the sustainability of an activity (both IT and non-IT). The following two sections discuss the application of IT to improve the sustainability of IT and then the application to a non-IT business activity.

50.3 Green for IT Practices

This section discusses Green for IT practices including Green Software, DC energy efficiency, and the LCA of products and services.

50.3.1 Green Software

Power-management features are becoming prevalent within hardware resulting in significantly improved hardware energy efficiency, with particularly high gains in mobile devices as a response to maximizing battery life. While hardware has been constantly improved to be energy efficient, software has not recorded a comparable track. The availability of increasingly efficient and cheaper hardware components has led designers up to now to neglect the energy efficiency of end-user software, which remains largely unexplored. While software does not consume power directly, software plays a critical role in the efficiency of the overall system as it interacts with power-consuming resources. Software causes the computations performed by the processor and is the root cause of all the consumption of the infrastructural layers within both a server and the DC (e.g., cooling, Uninterruptible Power Supply (UPS)).

The software development life cycle and related process management methodologies rarely consider energy efficiency as a design requirement. Software energy efficiency should be included in the initial design of software to optimize the efficiency of the software utilizing the hardware to satisfy a given set of functional requirements and workloads. Well-designed, efficient software should have good proportionality between the amount of useful work done and the amount of resources consumed [6]. In contrast, inefficient software demonstrates poor resource utilization to the amount of work done.

Effective resource management within software can contribute to the overall efficiency of the system. Where resources are over-allocated, or not efficiently used, the software can be responsible for lowering the efficiency of the entire system. The design of complex distributed software can affect the software energy efficiency. Well-known design issues that lower energy efficiency include sloppy programming techniques, excessive layering (deep inheritance trees leading to higher method invocation costs), code fragmentation (excessively small classes or small code objects inhibiting aggressive optimization), and overdesign (such as using databases to hold static configuration data) [7]. Software compilers cannot easily compensate for these design issues, resulting in lower energy efficiency [7]. An analysis [7] of the energy efficiency of software design has shown that:

- CPU is the component that absorbs most of the power (dependent on usage)
- Memory energy requirements are independent of use due to constant refreshing
- Hard disks consume most of the energy for their continuous spinning

The study concludes that an intelligent use of memory can shift the computational burden from the CPU to storage, possibly reducing the total energy consumption [7].

A concrete example of how software can be energy efficient is given by Steigerwald and Agrawal [8] for the efficiency of DVD playback software. When used on a notebook, is it better for the playback application to set up a large buffer and do less frequent optical drive reads or to keep the drive spinning? From an implementation perspective, there is not much difference between the two designs; however, the buffering strategy can add up to 20 min battery life. Within the analysis of the design of DVD applications, Steigerwald et al. [8] offer three key design considerations for energy-efficient software: (1) computational efficiency, (2) data efficiency, and (3) context awareness.

Computational efficiency: Reduce energy costs by improving application performance with respect to CPU utilization. The objective is to maximize the utilization of the CPU. The faster the workload can be completed, the sooner the CPU can return to idle and more energy can be saved. To achieve computational efficiency, use software techniques that achieve better performance such as efficient algorithms, multithreading, and vectorization.

Computational efficiency also extends to how the software interacts with the CPU. For example, a common design practice for threads waiting for a condition is to use a timer to periodically wake up to check if the condition has been satisfied. No useful work is being done as the thread waits, but each time it wakes up to check the condition, the CPU is forced to leave an idle power-managed state.

Ideally, applications should leverage an event-triggered mechanism to eliminate the need for time-based polling or, if possible, to move all periodic/polling activity to be batch processed.

Data efficiency: Reduce energy costs by minimizing data movement and using the memory hierarchy effectively. Data efficiency requires thinking about how an application reads and writes data (particularly I/O operations, such as read requests for a drive) and how it moves data around during execution. The DVD playback application is an example of data efficiency using I/O buffering to maximize I/O utilization by prefetching and caching. Other data efficiency techniques include:

- Software algorithms that minimize data movement
- Memory hierarchies that keep data close to processing elements
- Application software that efficiently uses cache memories

Data efficiency also covers the design of memory management. Data-efficient design will release memory that is no longer needed and watch for memory leaks. For example, a service that slowly leaks memory will over time allow its memory heap to grow to consume much of the system's physical memory. Even though the software does not actually need all this memory, it can restrict the opportunity to power manage memory since most of it has been allocated.

Context awareness: Reduce energy consumption by enabling applications to make intelligent decisions at runtime based on the current state of the system. Context-aware software knows the power state of the system and the current power policy, behaves appropriately, and responds to changes dynamically. These decisions are typically encapsulated in passive or active power policies. Passive power policies respond to a change in context by asking the user what action to take ("Switch to power-save mode?") or to acknowledge that the state change has occurred ("You have 10% battery left. OK?"). An active power policy would automatically take corrective actions, such as changing behavior to minimize energy consumption when a laptop is running on battery (i.e., dimming a screen when moving from AC to DC power sources).

Overall, the design of software can have a significant impact on its energy efficiency. If the software is less layered and more algorithmically efficient, it will consume less energy [7].

50.3.2 Data Center Energy Efficiency

With power densities of more than 100 times that of a typical office building, energy consumption is a central issue for DCs. Massive growth in the volumes of computing equipment, and the associated growth in areas such as cooling equipment, has led to increased energy usage and power densities within DCs. Trends toward cloud computing have the potential to further increase the demand for DC-based computing services [9].

The U.S. EPA estimates that servers and DCs are responsible for up to 1.5% of the total U.S. electricity consumption [10] or roughly 0.5% of U.S. GHG emissions for 2007. Power usage within a DC goes beyond the direct power needs of servers to include networking, cooling, lighting, and facilities management with power drawn for DCs ranging from a few kWs for a rack of servers to several tens of MWs for large facilities. While the exact breakdown of power usage will vary between individual DCs, Figure 50.3 illustrates an analysis of one DC where up to 88.8% of the power consumed was not used for computation; for every 100 W supplied to the DC, only 11.2 W was used for computation [10].

Air conditioners, power converters, and power transmission can use almost half of the electricity in the DC, and the IDC estimates that DC energy costs will be higher than equipment costs by 2015 [11]. The cost of operating a DC goes beyond just the economic bottom line; there is also an environmental cost. By 2020, the net footprint for DCs is predicted to be 259 $MtCO_2e$ [2]. There is significant potential to improve both the economic and environmental bottom line of DCs by improving their energy efficiency; however, a number of challenges exist.

The efficiency of a DC can be improved by using new energy-efficient equipment, improving airflow management to reduce cooling requirements, investing in energy management software, charging back

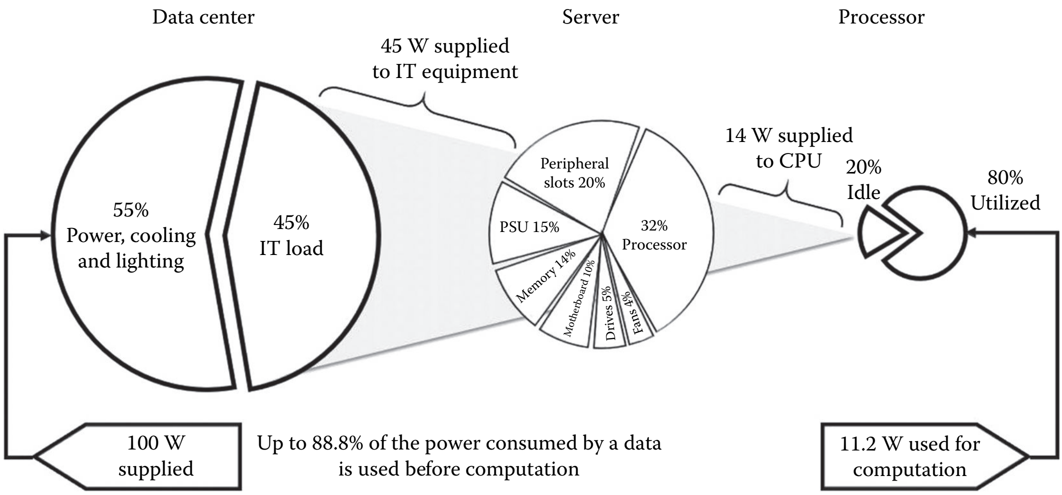

FIGURE 50.3 Example breakdown of power usage within a data center. (From Report to Congress on Server and Data Center Energy Efficiency Public Law 109–431, U.S. EPA, 2007.)

environmental impacts to consumers [12], and adopting environmentally friendly designs for DCs. In the remainder of this section, we will examine the most significant techniques for improving the energy efficiency within the DC, including virtualization, internal air management and cooling, and relevant metrics to understand the energy efficiency of a DC.

50.3.2.1 Virtualization

Virtualization is the creation of a virtual version (rather than actual physical version) of a computing resource such as a hardware platform, operating system, a storage device, or network resources. With virtualization, one physical server hosts multiple virtual servers as illustrated in Figure 50.4. Virtualization is a key strategy to reduce DC power consumption by consolidating physical server infrastructure to host multiple virtual servers on a smaller number of more powerful servers.

Virtualized DCs introduce additional degrees of freedom that are not available under traditional operating models where there is a hard binding between servers and the applications on which they run. Applications hosted in virtualized DCs run on virtualized operating systems. That is, the operating system does not run directly on the hardware, but it is mediated through a virtualization hypervisor. The hypervisor frees applications from a single physical host, allowing them to be moved around within a pool of servers to optimize the overall power and thermal performance of the pool. The loose binding between

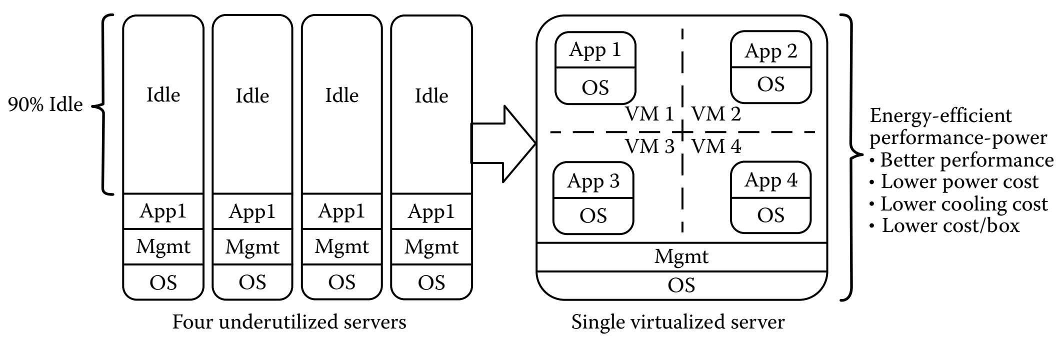

FIGURE 50.4 Saving achieved from virtualization of server resources.

applications and hosts allows treating a group of hosts as a pooled resources, allowing optimizations as a group that were not possible with individual machines, such as powering down servers during low demand.

50.3.2.2 Internal Air Management and Cooling

Air is the most common medium used to cool IT equipment. Moving air consumes energy; it is imperative that action is taken to ensure effective air management. How the air is supplied, how the exhaust heat is removed, what type of refrigeration cycle is utilized, and how the air circulates within the DC determine the energy efficiency of cooling [13,14].

Air segregation: Air mixing is an important issue with best practice to fully segregate hot and cold air. In the hot aisle, cold aisle configuration fans draw cool air from the front of the server, removing heat from the internal components and blowing the now heated air out through the back of the server chassis.

Air distribution strategies: Three common air cooling/distribution infrastructures are employed within the DC. (1) In *room-based (perimeter/peripheral) air-cooling*, cool air is delivered to the front of the server rack (cold aisle), typically through floor or overhead. The cool air is drawn through the servers and exhausted into the hot aisle. The hot air then propagates toward computer room air conditioners (CRACs) or computer room air handlers (CRAHs) at the peripheral of the room. (2) *Row-based* cooling is similar to perimeter cooling, but the individual CRACs/CRAHs are dedicated to a particular row of IT equipment as opposed to the room as a whole. (3) *Rack-based* cooling uses smaller CRAC/CRAH units associated with individual racks. In energy efficiency terms, row-based air distribution is typically an improvement on room-based cooling due to shortened air paths. However, rack-based cooling can be the most efficient given the reduced fan power required to move air within the confines of the rack itself.

Cooling: The main systems used to cool the DC include air-cooled direct expansion (DX) systems, glycol cooled systems, and water-cooled systems. Each utilizes a CRAC with an energy-hungry refrigeration cycle; a new practice is to use direct free cooling. Direct free cooling or airside economization is fast becoming an energy efficiency best practice. In climates that are suitable, air is supplied directly to the front of the IT equipment while the warmer exhaust air is ducted directly to the outside atmosphere. This essentially eliminates the refrigeration cycle providing what is typically called "free-cooling." In terms of redundancy and the percentage of the year when conditions are unfavorable, refrigeration-based backup is utilized.

50.3.2.3 Data Center Metrics

This section discusses a number of key metrics defined by the Green Grid* (a nonprofit group of IT enterprises formed in 2007) to understand the sustainability of a DC.

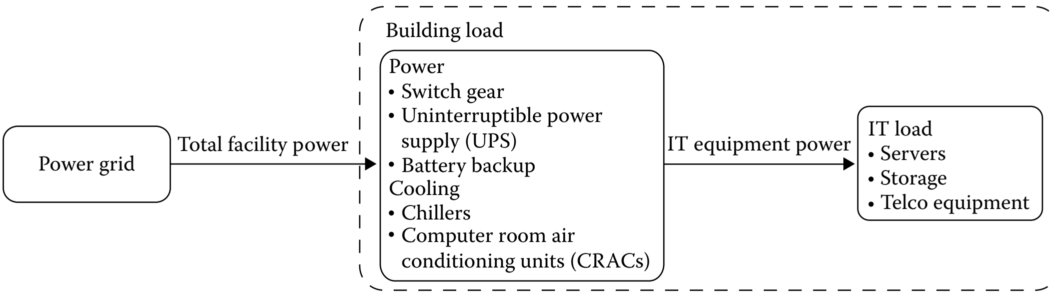
Power usage effectiveness/data center infrastructure efficiency: Power usage effectiveness (PUE) [15] is a measure of how efficiently a DC uses its power. PUE measures how much power the computing equipment consumes in contrast to cooling and other overhead uses. PUE is defined as follows:

$$\mathrm{PUE} = \frac{\text{Total Facility Power}}{\text{IT Equipment Power}}$$

The reciprocal of PUE is data center infrastructure efficiency (DCiE) and is defined as follows:

$$\mathrm{DCiE} = \frac{1}{\mathrm{PUE}} = \frac{\text{IT Equipment Power}}{\text{Total Facility Power}} \times 100\%$$

* http://www.thegreengrid.org



$$\text{Power usage effectiveness (PUE)} = \frac{\text{Total facility power}}{\text{IT equipment power}} \qquad \text{Data center infrastructure efficiency (DCiE)} = \frac{\text{IT equipment power}}{\text{Total facility power}}$$

FIGURE 50.5 PUE/DCiE calculation overview.

IT equipment power includes the load associated with all of the IT equipment, such as computing, storage, and network equipment, along with supplemental equipment used to monitor or otherwise control the DC including KVM switches, monitors, workstations, and laptops. *Total facility power* includes everything that supports the IT equipment load such as power delivery (UPS, generators, batteries, etc.), cooling system (chillier, computer room air conditioning units [CRACs], direct expansion air handler [DX] units, pumps, and cooling towers), compute, network, storage nodes, and other loads such as DC lighting.

Both PUE and DCiE, illustrated in Figure 50.5, are metrics that give an indication as to the use of power by supporting infrastructure of the DC. An ideal PUE would be 1.0; this means that no additional energy is consumed by the infrastructure that is supporting the IT load. The lower the PUE value the better, and conversely, the higher the DCiE value the better. If total power was 150 kW and IT power was 100 kW, then PUE would be 150/100 = 1.5; for DCiE, it would be 100/150 × 100 = 66%. This means that for every watt supplied to the IT equipment, half a watt is required to support it. A 2011 study by Koomey [16] estimates typical PUE between 1.93 and 1.83, with large DC operators such as Google, Yahoo, Facebook, and Microsoft reporting industry-leading PUE ratings in the 1.07–1.2 range.

While PUE/DCiE have proven to be an effective industry tool for measuring infrastructure energy efficiency, there is a need to measure the operational effectiveness of the DC. To this end, the Green Grid has defined a number of metrics [17] to measure dimensions including resource utilization and environmental impact. Water usage effectiveness (WUE) measures water usage to provide an assessment of the water used on-site for operation of the DC, while carbon usage effectiveness (CUE) measures DC-specific carbon emissions.

The xUE (PUE, WUE, CUE, etc.) family of consumption metrics does not tell the full story of the impacts of DCs on the environment. In order to understand the full environmental burden of a DC, a full life cycle analysis of the DC facilities and IT equipment is needed. These additional costs should not be underestimated. Take, for example, Microsoft's DC in Quincy, Washington, that consumes 48 MW (enough power for 40,000 homes) of power. In addition to the concrete and steel used in the construction of the building, the DC uses 4.8 km of chillers piping, 965 km of electrical wire, 92,900 m^2 of drywall, and 1.5 metric tons of batteries for backup power. Each of these components has its own impact that must be analyzed in detail; the means by which this is done is called an life cycle analysis (LCA).

50.3.3 Life Cycle Assessment

Understanding the impacts of an IT product or IT service requires an analysis of all potential impacts during its entire life cycle. An LCA, also known as life cycle analysis, is a technique to systematically identify resource flows and environmental impacts associated with all the stages of product/service provision [18]. The LCA provides a quantitative cradle-to-grave analysis of the product/services global environmental costs (i.e., from raw materials through materials processing, manufacture, distribution, use,

repair and maintenance, and disposal or recycling). The demand for LCA data and tools has accelerated with the growing global demand to assess and reduce GHG emissions from different manufacturing and service sectors [18].

LCA can be used as a tool to study the impacts of a single product to determine the stages of its life cycle with most impact. LCA is often used as a decision support when determining the environmental impact of two comparable products or services.

50.3.3.1 Four Stages of LCA

The LCA standards, ISO 14040 and 14044 [19], follow a process with four distinct phases:

1. *Goal and scope definition*: It is important to ask the right question to ensure whether the LCA is successful. The first step in this process is the framing of the key questions for the assessment. Typical steps are to define the goal(s) of the project, determine what type of information is needed to inform decision makers, define functional units (environmental impact, energy efficiency, life span, cost per use, etc.), define the system boundaries, study perspective, allocation principles, environmental impact assessment categories, and level of detail.
2. *Inventory analysis*: The second phase involves data collection and modeling of the product/service system with process flow models and inventories of resource use and process emissions. The data must be related to the functional unit defined in the goal and scope definition and include all data related to environmental (e.g., CO_2) and technical (e.g., intermediate chemicals) quantities for all relevant unit processes within the study boundaries that compose the product system. Examples of inputs and outputs include materials, energy, chemicals, air emissions, water emissions, solid waste, radiation, or land use. This results in a life cycle inventory that provides verified information about all inputs and outputs in the form of elementary flows to and from the environment from all the unit processes involved in the study.
3. *Impact assessment*: The third phase evaluates the contribution to selected impact assessment categories, such as "Climate Change," "Energy Usage," and "Resource Depletion." Impact potential of the inventory is calculated and characterized according to the categories. Results can then be normalized across categories (same unit) and weighted according to the relative importance of the category.
4. *Interpretation*: The final phase involves interpretation of the results to determine the level of confidence and to communicate them in a fair, complete, and accurate manner. This is accomplished by identifying the data elements that contribute significantly to each impact category, evaluating the sensitivity of these significant data elements, assessing the completeness and consistency of the study, and drawing conclusions and recommendations based on a clear understanding of how the LCA was conducted and how the results were developed.

50.3.3.2 CRT Monitor vs LCD Monitor: Life Cycle Assessment

The U.S. Environmental Protection Agency's Design for the Environment program conducted a comprehensive environmental LCA of a traditional cathode ray tube (CRT) and a newer LCD monitor. The objective of the study [20] was to evaluate the environmental and human health life cycle impacts of functionally equivalent 17-in. CRT and 15-in. LCD monitors. The study assessed the energy consumption, resources input, and pollution produced over the lifetime of the equipment. The cradle-to-grave analysis was divided into three stages: (1) cradle-to-gate (manufacturing), (2) use, and (3) end-of-life (disposing or reusing). Each stage was assessed for the energy consumed, materials used in manufacturing along with associated waste. Components manufactured in different locations, where energy sources can differ due to the way local energy is produced, such as coal vs. nuclear, were taken into account. A sample of the results from a life cycle environmental assessment is presented in Table 50.1.

In summary, the LCA concluded that LCD monitors are about 10 times better for resource usage and energy use and 5 times better for landfill use. However, LCDs are only 15% better for global warming due to the fact that the LCD manufacturing process uses sulfur hexafluoride, a significant GHG.

TABLE 50.1 Life Cycle Analyses of CRT and LCD Monitors

	17″ CRT	15″ LCD
Total input material	21.6 kg	5.73 kg
Steel	5.16 kg	2.53 kg
Plastics	3 lb	1.78 kg
Glass	0.0 kg	0.59 kg
Lead-oxide glass	9.76 kg (0.45 lb of lead)	0.0 kg
Printed circuit boards (PCBs)	0.85 kg	0.37 kg
Wires	0.45 kg	0.23 kg
Aluminum	0.27 kg	0.13 kg
Energy (in manufacturing)	20.8 GJ	2.84 GJ
Power drawn	126 W	17 W
Energy (use—5 years' full power)	2.2 GJ	850 MJ

50.4 IT for Green Practices

50.4.1 Green Information Systems

As sustainable information is needed at both the macro and micro levels, it will require a multilevel approach that provides information and metrics that can drive high-level strategic corporate/regional sustainability plans, as well as low-level actions like improving the energy efficiency of an office worker. Relevant and accurate data, information, metrics, and Green Performance Indicators (GPIs) are important key to support sustainable practices, and the development of information systems that support this information need has led to the emergence of Green IS as a field in itself. There is substantial potential for Green IS to bring together business processes, resource planning, direct and indirect activities, and extended supply chains to effect positive changes across the entire activities of governments, organizations, and individuals. Green IS has been applied to a number of problems, from optimization of logistical networks [21], to buildings, DCs [12], and even cities. Within organizations, Green IS is the engine driving both the strategic and operational management of sustainability issues. Organizations pursuing a sustainability agenda will need to consider their Green IS to be a critical part of their operations [22]. This presents many challenges for Green IS research, and Melville [23] has outlined these under six themes:

1. *Context*: How do the distinctive characteristics of the environmental sustainability context, such as values and altruism, affect intention to use and usage of information systems for environmental sustainability?
2. *Design*: What design approaches are effective for developing information systems that influence human actions about the natural environment?
3. *Causality*: What is the association between information systems and organizational sustainability performance?
4. *New business models*: What is the association between IS and business models from an efficiency and environmental perspective?
5. *Systems approaches*: How can system approaches shed light on organizational and environmental outcomes that result from the use of IS for environmental sustainability?
6. *Models/metrics*: What are the multilevel models and metrics that encompass enterprise-wide sustainability initiatives?

50.4.1.1 Energy Informatics

The research field of energy informatics [22], a subfield of Green IS, recognizes the role that information systems can play in reducing energy consumption and thus CO_2 emissions. Energy informatics is concerned with analyzing, designing, and implementing systems to increase the efficiency of energy

demand and supply systems. The core idea requires the collection and analysis of energy data to support optimization of energy. Watson [22] expresses this as:

$$\text{Energy} + \text{Information} < \text{Energy}$$

The Energy Informatics Framework [22], as illustrated in Figure 50.6, addresses the role of the information systems in the management and optimization of energy. The key components of the framework are as follows:

Supply and demand: There are two parties to any energy consumption transaction: a supplier and a consumer. Both sides have a common need for information to manage the flow of the resources they deliver and consume.

Energy system technologies: Three types of technology are present in an intelligent energy system:

1. *Flow network*: a set of connected transport components that supports the movement of continuous matter (e.g., electricity, oil, air, and water) or discrete objects (e.g., cars, packages, containers, and people).
2. *Sensor network*: a set of spatially distributed devices that reports the status of a physical item or environmental condition (e.g., air temperature, location of a mobile object) providing data that can be analyzed to determine the optimum use of a flow network.
3. *Sensitized object*: a physical good that a consumer owns or manages and has the capability to sense and report data about its use (i.e., GPS in a car). They provide information about the use of an object so that a consumer is better informed about the impact of the object on their finances and the environment. In addition, there needs to be remote control of the state of some sensitized objects so that suppliers and consumers can manage demand (i.e., smart appliances).

Information system: An information system ties together the various elements to provide a complete solution. It has several important functions from collecting data from the sensor network and feeding them into flow optimization algorithms, to transmitting data to automated controllers in the flow network to dynamically change a network based on the output of the optimization algorithms. The information system is also responsible for information provision to flow network managers, consumers, and governments about the consumption of resources. They can also enable consumers to automate or control object usage to reduce energy consumption.

Key stakeholders: The three most critical stakeholders in typical energy supply/demand systems are *suppliers* (provide energy/services, manage flow networks), *governments* (regulation), and *consumers* (user of the resource).

Eco-goals: The sustainability literature has identified three broad sustainability goals: *eco-efficiency* (ecological friendly competitively priced goods and services), *eco-equity* (social responsibility), and *eco-effectiveness* (working on the right products and services and systems).

The energy informatics framework provides a solid basis for managing different resource types with a Green IS (i.e., logistics [21]). Having discussed a number of sustainable IT practice, attention will now be turned to the challenges faced by IT organizations as they put sustainable IT best practice into action.

50.4.2 Sustainable IT in the Enterprise

To deliver on the promise of sustainable IT, IT organizations need to develop a sustainable IT capability to deliver benefits both internally and across the enterprise. However, due to the new and evolving nature of the field, few guidelines and guidance on best practices are available. Organizations face many challenges in developing and driving their overall sustainable IT strategies and programs as follows:

- The complexity of the subject and its rapid evolution
- The lack of agreed-upon and consistent standards

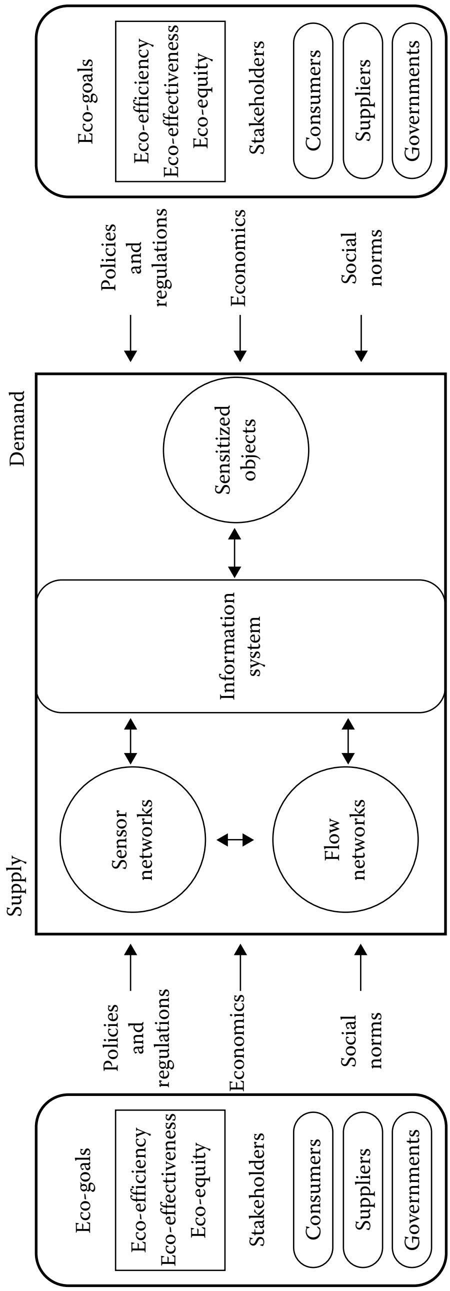


FIGURE 50.6 Energy informatics framework. (From Watson, R.T. et al., *MIS Quart.*, 34(1), 23, 2010.)

- Changing stakeholder expectations
- The lack of subject-matter expertise
- The need for new metrics and measures
- Evolving and increasing regulations and legislation around the world

Unfortunately, organizations often do not exploit IT's full potential in their efforts to achieve sustainability. Business and IT leaders frequently cannot find satisfactory answers to questions such as the following:

- Does the organization recognize IT as a significant contributor to its overall sustainability strategy?
- How is IT contributing to the organization's sustainability goals?
- What more could IT do to contribute to those goals?
- Are there clear measurable goals and objectives for sustainable IT?

IT departments face additional challenges specific to new IT methods and tools, industry metrics, and standards bodies as well as a general lack of relevant information such as power consumption quantifications. The challenge for IT departments is further complicated by the fact that sustainability is an enterprise-wide issue that spans the full value chain. The business is facing its own challenges in developing clear strategies and priorities to address a burning problem in such a dynamic and uncertain environment. It might lack the maturity to fully include sustainable IT in its efforts. This puts the onus on the IT organization to deliver sustainable IT benefits across the organization. In the remainder of this section, we examine two tools that can help an IT organization to develop a sustainable IT program: (1) a set of principles for Sustainable Enterprise IT and (2) the Sustainable Information Communication Technology-Capability Maturity Framework (SICT-CMF) from the Innovation Value Institute (IVI).

50.4.3 Sustainable IT Principles

In order to drive the adoption of sustainable IT, it is important for an IT organization to develop a clear set of IT sustainability principles for their activities. Sustainable IT principles are a set of aspirational statements to provide guidance on sustainable IT practices. An example of principles from the IT organization of Intel is described in Table 50.2 [24]. Within Intel IT, the principles play an important role in decision-making and are included in measurement models, standards, and processes. The criteria set out by the principles may also influence programs toward suppliers with sustainable business practices.

TABLE 50.2 Examples of Sustainable IT Principles from Intel IT

Principle	Example Actions
Consciously manage our capabilities	Include sustainability value and impacts in our proposals, measurements, and decision-making
Select sustainable suppliers	Work with our supplier managers to ensure our purchases represent and support sustainable business practices
Enable the organization to meet global sustainability compliance	Proactively monitor global regulations and requirements to ensure IT's and the organization's compliance
Measure, monitor, and optimize consumption	Reduce consumption and actively manage resources using sustainability metrics
Enable sustainable facilities	Work with Technology and Manufacturing Group (TMG) and Corporate Services (CS) to use IT capability to reduce resource consumption within TMG and CS IT capabilities to reduce resource consumption
Enable IT sustainability behavior	Create global awareness of IT sustainability that encourages IT employees to be corporate role models
Enable travel avoidance	Showcase all IT collaboration technologies across Intel
Promote IT's sustainability innovations across Intel and externally	Support sustainability innovations in our IT solutions and share those successes across Intel and externally

50.4.4 Capability Maturity Framework for Sustainable Information Communication Technology

The SICT-CMF gives organizations a vital tool to manage their sustainability capability [25,26]. The framework provides a comprehensive value-based model for organizing, evaluating, planning, and managing sustainable information communication technology (ICT) capabilities. The framework targets the broader scope of ICT to include communication technologies such as online collaboration tools, video conferencing, and telepresence, which can have positive impacts on sustainability (i.e., reduce business travel). Using the framework, organizations can assess the maturity of their SICT capability and systematically improve capabilities in a measurable way to meet the sustainability objectives. The SICT-CMF offers a comprehensive value-based model for organizing, evaluating, planning, and managing SICT capabilities, and it fits within the IVI's IT-CMF [27]. The SICT-CMF complements existing approaches for measuring SICT maturity, such as the G-readiness framework (which provides a benchmark score against SICT best practices [28,29]) or the Gartner Green IT Score Card (which measures corporate social responsibility compliance).

The SICT-CMF assessment methodology determines how SICT capabilities are contributing to the business organization's overall sustainability goals and objectives. This gap analysis between what the business wants and what SICT is actually achieving positions the SICT-CMF as a management tool for aligning SICT capabilities with business sustainability objectives.

The framework focuses on the execution of four key actions for increasing SICT's business value:

- Define the scope and goal of SICT
- Understand the current SICT capability maturity level
- Systematically develop and manage the SICT capability building blocks
- Assess and manage SICT progress over time

50.4.4.1 Defining the Scope and Goal

First, the organization must define the scope of its SICT effort. As a prerequisite, the organization should identify how it views sustainability and its own aspirations. Typically, organizational goals involve one or more of the following:

- Develop significant capabilities and a reputation for environmental leadership.
- Keep pace with industry or stakeholder expectations.
- Meet minimum compliance requirements and reap readily available benefits.

Second, the organization must define the goals of its SICT effort. It is important to be clear on the organization's business objectives and the role of SICT in enabling those objectives. Having a transparent agreement between business and IT stakeholders can tangibly help achieve those objectives. Significant benefits can be gained even by simply understanding the relationship between business and SICT goals.

50.4.4.2 Capability Maturity Levels

The framework defines a five-level maturity curve [26] for identifying and developing SICT capabilities (Figure 50.7):

1. *Initial*: SICT is ad hoc; there is little understanding of the subject and few or no related policies. Accountabilities for SICT are not defined, and SICT is not considered in the systems life cycle.
2. *Basic*: There is a limited SICT strategy with associated execution plans. It is largely reactive and lacks consistency. There is an increasing awareness of the subject, but accountability is not clearly established. Some policies might exist but are adopted inconsistently.

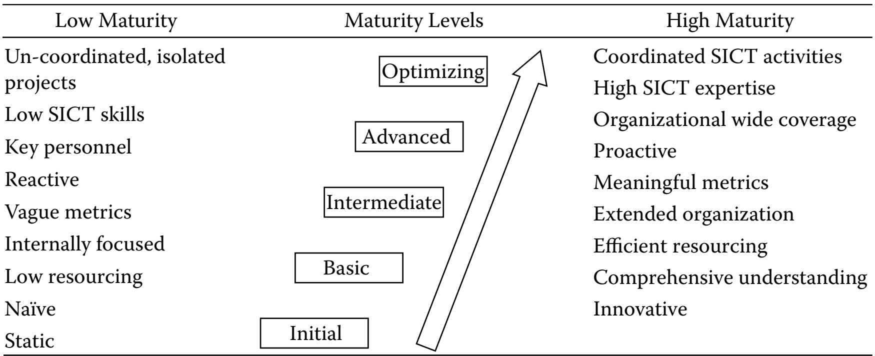

FIGURE 50.7 Comparison of low and high maturity of SICT.

3. *Intermediate*: An SICT strategy exists with associated plans and priorities. The organization has developed capabilities and skills and encourages individuals to contribute to sustainability programs. The organization includes SICT across the full systems life cycle, and it tracks targets and metrics on an individual project basis.
4. *Advanced*: Sustainability is a core component of the IT and business planning life cycles. IT and business jointly drive programs and progress. The organization recognizes SICT as a significant contributor to its sustainability strategy. It aligns business and SICT metrics to achieve success across the enterprise. It also designs policies to enable the achievement of best practices.
5. *Optimizing*: The organization employs SICT practices across the extended enterprise to include customers, suppliers, and partners. The industry recognizes the organization as a sustainability leader and uses its SICT practices to drive industry standards. The organization recognizes SICT as a key factor in driving sustainability as a competitive differentiator.

This maturity curve serves two important purposes. First, it is the basis of an assessment process that helps to determine the current maturity level. Second, it provides a view of the growth path by identifying the next set of capabilities an organization should develop to drive greater business value from SICT. A contrast of low and high levels of sustainable ICT is offered in Figure 50.1.

50.4.4.3 SICT Capability Building Blocks

While it is useful to understand the broad path to increasing maturity, it is more important to assess an organization's specific capabilities related to SICT. The SICT framework consists of nine capability building blocks (see Table 50.3) across the following four categories:

1. *Strategy and planning,* which includes the specific objectives of SICT and its alignment with the organization's overall sustainability strategy, objectives, and goals
2. *Process management,* which includes the sourcing, operation, and disposal of ICT systems, as well as the provision of systems based on sustainability objectives and the reporting of performance
3. *People and culture,* which defines a common language to improve communication throughout the enterprise and establishes activities to help embed sustainability principles across IT and the wider enterprise
4. *Governance,* which develops common and consistent policies and requires accountability and compliance with relevant regulation and legislation

The first step to systematically develop and manage the nine capabilities within this framework is to assess the organization's status in relation to each one.

The assessment begins with the survey of IT and business leaders to understand their individual assessments of the maturity and importance of these capabilities. A series of interviews with key stakeholders augments the survey to understand key business priorities and SICT drivers, successes

TABLE 50.3 Capability Building Blocks of SICT

Category	Capability Building Block	Description
Strategy and planning	Alignment	Define and execute the ICT sustainability strategy to influence and align to business sustainability objectives
	Objectives	Define and agree on sustainability objectives for ICT
Process management	Operations and life cycle	Source (purchase), operate, and dispose of ICT systems to deliver sustainability objectives
	ICT-enabled business processes	Create provisions for ICT systems that enable improved sustainability outcomes across the extended enterprise
	Performance and reporting	Report and demonstrate progress against ICT-specific and ICT-enabled sustainability objectives, within the ICT business and across the extended enterprise
People and culture	Adoption	Embed sustainability principles across ICT and the extended enterprise
	Language	Define, communicate, and use common sustainability language and vocabulary across ICT and other business units, including the extended enterprise, to leverage a common understanding
Governance	External compliance	Evangelize sustainability successes and contribute to industry best practices
	Corporate policies	Enable and demonstrate compliance with ICT and business sustainability legislation and regulation. Require accountability for sustainability roles and decision-making across ICT and the enterprise

achieved, and initiatives taken or planned. In addition to helping organizations understand their current maturity level, the initial assessment provides insight into the value placed on each capability, which will undoubtedly vary according to each organization's strategy and objectives. The assessment also provides valuable insight into the similarities and differences in how key stakeholders view both the importance and maturity of individual capabilities and the overall vision for success.

Figure 50.8 shows an example of consolidated survey results, resulting in an overall maturity level for each capability building block. This organization is close to level-three maturity overall but is less mature in some individual capabilities. It views alignment and objectives under the strategy and planning category as the most important capability building blocks, but it has not achieved level-three maturity in these areas. It also views operations and life cycle as important capabilities, but its maturity level for that building block is even lower (level 2.4).

50.4.4.4 Assessing and Managing SICT Progress

With the initial assessment complete, organizations will have a clear view of current capability and key areas for action and improvement. However, to further develop SICT capability, the organization should assess and manage SICT progress over time by using the assessment results to:

- Develop a roadmap and action plan
- Add a yearly follow-up assessment to the overall IT management process to measure over time both progress and the value delivered from adopting SICT

Agreeing on stakeholder ownership for each priority area is critical to developing both short-term and long-term action plans for improvement. The assessment results can be used to prioritize the opportunities for quick wins—that is, those capabilities that have smaller gaps between current and desired maturity and those that are recognized as more important but might have a bigger gap to bridge.

The assessment of sustainable IT was carried out in a number of global firms over the last 2 years. The assessment methodology included interviews with stakeholder from both the IT organizations and the business organization, including individuals involved with IT and corporate sustainability programs. The average results for the SICT maturity of the examined organizations are presented in Table 50.4.

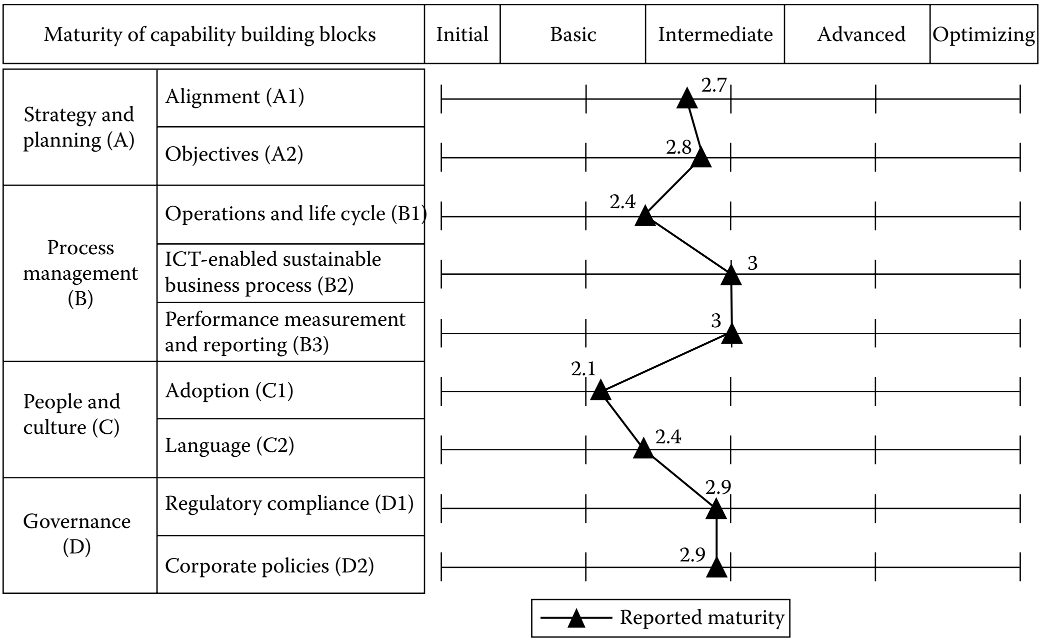

FIGURE 50.8 Aggregated result for the current maturity level from the assessment.

TABLE 50.4 Average SICT Maturity

Category	Capability	AVR CBB	Low	High	Diff	AVR Cat
Strategy and planning	Alignment	2.61	2.38	3.2	0.82	2.51
	Objectives	2.41	2.08	2.8	0.72	
Process management	Operations and life cycle	2.46	2.32	2.8	0.48	2.52
	ICT-enabled business processes	2.70	2.5	3	0.5	
	Performance and reporting	2.40	1.2	3	1.8	
People and culture	Adoption	2.03	1.89	2.3	0.41	2.18
	Language	2.33	2	2.9	0.9	
Governance	External compliance	2.19	1.8	2.9	1.1	2.24
	Corporate policies	2.28	1.4	2.9	1.5	

50.5 Research Directions

Many organizations think that sustainability requires a significant transformational change, yet the ultimate goal is to embed sustainability into business-as-usual activities. Improving sustainability performance [26], especially through changing the way an organization operates, requires a number of practical steps that will include the need for a systematic approach for information-gathering and analysis [30].

While organizations are fighting a data deluge within their information systems [31], there is a significant lack of data on sustainability concerns. A 2010 survey of more than 600 chief information officers and senior IT managers highlighted that few organizations are performing well at measuring the effectiveness of their sustainability efforts [29]. The paucity of sustainable information within organizations is a significant challenge and one that needs to be addressed if sustainable IT efforts are to deliver on their potential. Determining the granularity for effective sustainable data is not well understood, and research is needed to define the appropriate level of usefulness [22]. The appropriateness of information will also be highly dependent on the stakeholders and the task

or decision at hand. Sustainable IT will need to be flexible to provide the appropriate level of information for the given situation.

Emerging next-generation smart environments such as Smart Grids, Smart Cities, and Smart Enterprises are complex systems that require a complete and holistic knowledge of their operations for effective decision-making. Multiple information systems currently operate within these environments and real-time decision support will require a system of systems (SoS) approach to provide a functional view of the entire environment to understand, optimize, and reinvent processes. The required SoS will need to connect systems that cross organizational boundaries, come from multiple domains (i.e., finance, manufacturing, facilities, IT, water, traffic, waste, etc.), and operate at different levels (i.e., region, district, neighborhood, building, business function, individual). These SoS pose many significant challenges, including the need for flexible mechanisms for information interoperability that require overcoming conceptual barriers (both syntax and semantic) and technological barriers. Overcoming these challenges will require rethinking the design and approach to interoperability of green information systems using decentralized information management approaches such as Semantic Web and Linked Data [32].

50.6 Summary

The first wave of sustainable IT focused on the Greening of IT (i.e., software, DCs, etc.), and the next wave of sustainable IT will tackle the broad sustainability issues outside of IT (i.e., energy management, logistics, etc.). Sustainability requires information on the use, flows, and destinies of energy, water, and materials including waste, along with monetary information on environment-related costs, earnings, and savings. There is substantial potential for sustainable IT to bring together business processes, resource planning, direct and indirect activities, and extended supply chains to effect positive changes across the entire activities of governments, organizations, and individuals.

Glossary

Energy: A physical quantity that describes the amount of work that can be performed by a force. A device that is energy efficient requires less energy for its “work” or task than its energy-inefficient counterpart. Energy can be expressed in units such as Joules.

Heat: Resistive heat is a natural by-product of running current through a conductor. Heat is a form of energy, and engineers strive to minimize heat release in computer design to minimize the need for cooling (typically by a fan).

Joule: Standard unit of energy measurement or work in the International System of Units.

Power: The rate at which energy is transferred, used, or transformed per unit of time. Within IT, power is typically measured in Watts, where a Watt equals 1 J/s. For example, a light bulb rated at 60 W consumes 60 J in 1 s.

Further Readings

- *IEEE IT Professional*, Special issue on Green IT 13(1): The January/February 2011 issue of IT Professional focused on Green IT and its transition toward sustainable IT. Articles focus on topics including sustainable IT, assessment of Green IT practices, power consumption of end-user PCs browsing the web, and corporate strategies for Green IT.

- *Harnessing Green IT*: *Principles and Practices,* (2012) S. Murugesan and G. R. Gangadharan (eds.), Wiley—IEEE, ISBN-10: 1119970059: This book presents and discusses the principles and practices of making computing and information systems greener—environmentally sustainable—as well as various ways of using information technology (IT) as a tool and an enabler to improve the environmental sustainability. The book comprehensively covers several key aspects of Green IT—green technologies, design, standards, maturity models, strategies, and adoption—and presents holistic approaches to greening IT encompassing green use, green disposal, green design, and green manufacturing.
- *Green Business Process Management–Towards the Sustainable Enterprise*, (2012), J. vom Brocke, S. Seidel, and J. Recker (eds.), Springer, ISBN-10: 3642274870. This volume consolidates the state-of-the-art knowledge about how business processes can be managed and improved in light of sustainability objectives. This book presents tools and methods that organizations can use in order to design and implement environmentally sustainable processes and provide insights from cases where organizations successfully engaged in more sustainable business practices.
- IT@Intel: IT Best Practices: (http://www.intel.com/content/www/us/en/it-management/intel-it/intel-it-best-practices.html) The IT @ Intel best practices portal gives insights into how an IT department can be run like a business, enabling the organization to take advantage of new technologies. In addition to general IT topics, white paper covers topics on data center energy efficiency, sustainable IT roadmaps, smart buildings, and Green Software.
- *Green IT/Sustainable IT columns in IEEE Computer and IEEE Intelligent Systems*: At the time of writing, both IEEE Computer and IEEE Intelligent Systems had regular columns dedicated to Green IT and sustainable IT. These columns covered many topics including, energy management, server power management, energy awareness, Green Software, and consumption-based metrics.

Business Continuity

Nijaz Bajgoric
University of Sarajevo

51.1 Introduction

As more and more businesses are operating in an e-business environment, they are under pressure to "keep their business in business" continuously. It is particularly important to ensure this for data/information availability, because continuous data access and availability are sought by employees, current and prospective customers, suppliers, and other stakeholders. Therefore, most businesses today seek for an information system infrastructure that is running 24/7/365, ensuring that data and applications are continuously available.

Information technologies have brought new opportunities for businesses in their efforts to increase their profits, reduce the costs, enhance the quality of products and services, improve relations with customers, and ease data access. However, at the same time, IT-related problems have produced new business risks as well. Unavailable data, stolen or lost computers, hardware glitches, server operating system crashes, application software errors, damaged backup tapes, broken data communication connections, a destroyed computer center due to several types of natural disasters, hackers' activities, and power outages are just some situations that may cause interruptions in business computing and affect the whole business.

The nature and characteristics of IT-associated risks have dramatically changed over two recent decades. While some 20–30 years ago an IT-related problem on a computer center's mainframe was viewed only as a "technical" problem causing a delay in, for instance, payroll system schedule, today similar problem may affect financial results and a corporation's competitive position or even bring the whole business into a halt. Unlike those times when most businesses operated on a "five-days-a-week" and "9 am–5 pm" basis, currently, it is common for most businesses to run on a 24/7/365 schedule. Hence, the role of business computing is becoming more important than ever with a special emphasis on becoming "continuous computing." It is no longer just about faster data processing, management of data, support for decision making, but rather about "keeping business in business." Business technology—a buzzword coined by Forrester (2007)—represents one of the major shifts in the way

people think about computers in IT history. According to Forrester, business technology is based on two key ideas: (1) IT risks are business risks and (2) IT opportunities are now business opportunities.

"Business continuity" (BC) or "business continuance" is a general term that emphasizes the ability of a business to continue with its operations and services even if some sort of failure or disaster on its computing platform occurs. Therefore, BC is rather to be defined as an ultimate objective of modern business with regard to capability of its information system to provide both continuous computing and business resilience. Modern business seeks for an information infrastructure that is going to be always on with zero downtime or highly available with near-zero-downtime. Symantec's Small and Medium Business (SMB) Disaster Preparedness Survey (2011) revealed that disasters can have a significant financial impact on SMBs. At the time of this survey, the median cost of downtime for an SMB was $12,500 per day. Aberdeen Group found recently (Csaplar, 2012) that between June 2010 and February 2012, the cost per hour of downtime increased on average by 65%. In February 2010, the average cost per hour of downtime was reported to be about $100,000.

51.2 Business Continuity Defined and Impact on Practice

51.2.1 Business Continuity Defined

The concept of BC reflects the dependence of modern business on its information system infrastructure. If an enterprise's information system is up with mission-critical applications running and providing services to end users, business is said to be "in business." When an application server running a critical e-business application goes down for any reason, business simply becomes "out of business." Therefore, the process of addressing, mitigating, and managing the IT risks has become one of the major issues in organizational IT management.

Today's IT-related threats/risks that may cause system unavailability and hence affect the business can be classified into the following major categories:

- Technical glitches and/or hardware component failures within the IT infrastructure: processors, memory chips, mainboards, hard disks, disk controllers, tapes and tape drives, network cards, fans, power supply unit.
- Physical damage to/thefts of IT centers, servers, client computers, mobile devices, or communication/networking devices.
- Operating system crashes: crashes of server operating systems that run enterprise servers and make server applications available to end users.
- Internal threats such as intentional malicious or retaliation acts of disgruntled IT staff and other insiders including former employees, operational errors, careless behavior of users and system administrators, human errors such as accidental or deliberate deletion of system and configuration files, unskilled operations, mistakes by well-intentioned users, and hazardous activities including sabotage, strikes, epidemic situations, and vandalism.
- External threats that range from individuals hacking the Internet sites on curiosity basis to organized criminals and professionals working for industrial espionage purposes. These include Internet-based security threats such as viruses, malware, botnets, malicious code, Denial-of-Service or Distributed Denial-of-Service (DoS or DDOS) attacks, spam, intrusion attacks, phishing, and moles.
- File or process-based problems such as corrupted configuration files, broken processes or programs, and file system corruption.
- Application software defects: bugs in programs, badly integrated applications, user interventions on desktop computers, corrupted files, etc.
- LAN/WAN/Internet disconnections, hardware failures on data communication devices, software problems on network protocols, Domain Controllers, gateways, Domain Name Server (DNS) servers, Transmission Control Protocol/Internet Protocol (TCP/IP) settings, etc.

- Loss or leaving of key IT personnel: bad decisions on IT staffing and retention, particularly with regard to system administrators.
- Natural threats such as fire, lightning strike, flood, earthquake, storm, hurricane, tornado, snow, and wind.

These threats are shown in Figure 51.1.

In addition to several types of hardware failures, physical damages on computer systems, and natural threats, a number of threats coming from inside and outside of computer centers may cause system unavailability. These threats are in most cases addressed to enterprise servers given their role in modern business computing. Particularly, external threats require more attention as the servers are, by default, as follows:

- Accessible, available, tend to be always on, and running on continuous basis. Therefore, they are subject to continuous attacks from external attackers. Server-oriented attacks are much more expected than attacks to personal systems.
- Having several configuration files that can be misused (e.g., /etc/passwd file, /etc/hosts file, allow/deny access files on Unix/Linux).

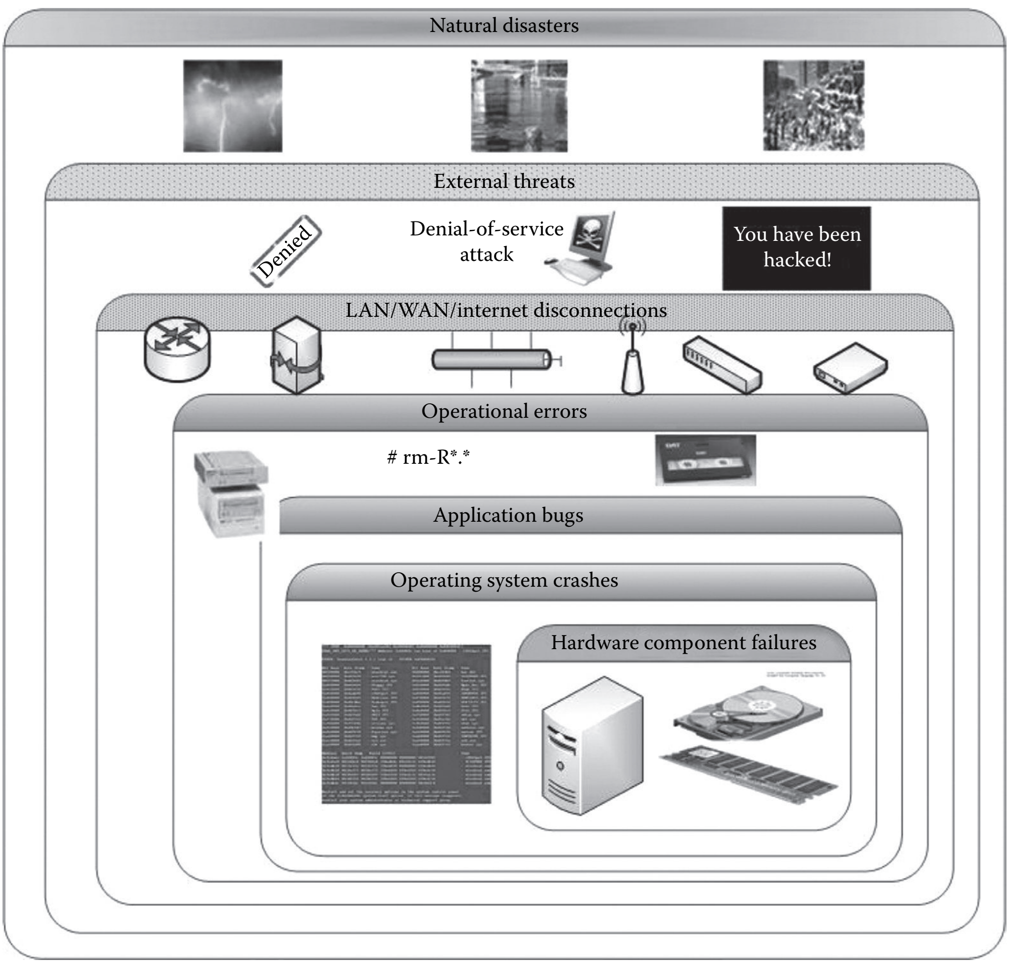

FIGURE 51.1 Major IT-related threats and risks.

- Having a number of services set on the "on" mode (open, active) after installation that opens the door for possible attacks.
- Storing business-critical applications and end user data to be accessed on remote basis, instead of keeping data on desktop/portable computers.

Addressing these threats leads to the process of mitigating (reducing) downtime situations and achieving continuous computing. Operating environment that facilitates continuous computing is a hardware–software platform that encompasses several technologies that are necessary for efficient and effective business-critical applications. Its characteristics will be discussed at a more detailed level in later sections.

Sumner (2009) unveiled the results of a study of top security threats perceived by organizations with over 500 employees as (1) deliberate software attacks, (2) technical software failures or errors, (3) acts of human error or failure, (4) deliberate acts of espionage or trespass, and (5) deliberate acts of sabotage or vandalism. ITIC Report (2009) unveiled the fact that server hardware and server operating system reliability have improved vastly since the 1980s, 1990s, and even in just the last 2–3 years. While technical bugs still exist, the number, frequency, and severity have declined significantly. This report underscores the fact that with few exceptions, common human error poses a bigger threat to server hardware and server operating system reliability than technical glitches. Adeshiyan et al. (2010) stated that traditional high-availability and disaster recovery solutions require proprietary hardware, complex configurations, application-specific logic, highly skilled personnel, and a rigorous and lengthy testing process. They provide some guidelines on how virtualization can be used in order to achieve high availability (HA) and disaster recovery.

The term "continuous computing" will be defined in the following way:

- By computing, we refer to an information system implemented by using information and communication technologies.
- By continuous, we refer to the ability of an information system to have both applications and data available on continuous basis for end users, customers, suppliers, and other stakeholders.

When an application server running business-critical or any other business application is not operational, it is said to be "down" or "off." The time in which it does not operate is called "downtime." Downtime refers to a period of time that a computing infrastructure component is not functioning, in most cases as a result of some system failure such as hardware component failures, operating system crashes, application software malfunctioning, regular maintenance, and so on.

Downtime can be planned or expected, and unplanned or unexpected (undesired). Planned downtime is a result of planned operations due to several administrative tasks or reasons for shutting application and/or operating system down. On the server side, it includes administrative tasks on servers, server operating systems, applications, LANs, and the WAN. Planned downtime is scheduled, usually duration-fixed, due to planned operations made mainly by system administrators such as regular data backups, hardware maintenance and upgrade, operating system upgrades and updates, application updates, and periodic events such as different types of hardware and software testing processes. Unplanned downtime is unanticipated, duration-variable downtime of a computer system due to several types of natural disasters, power outages, infrastructure failures, hardware or software failures, human errors, lack of proper skills, etc. Recent advances in information technologies allow several administrative operations on servers, both hardware and software interventions, without halting the system down.

The opposite is uptime. Uptime is a measure of the time a computer system such as a server has been "up," running and providing services. It has three main dimensions that reflect the capabilities of a server platform to be available, reliable, and scalable.

- *High availability* refers to the ability of a server operating environment to provide end users an efficient access to data, applications, and services for a high percentage of uptime while minimizing both planned and unplanned downtime. It is the ability of a system (server, operating system,

application, network) to continue with its operation even in cases of hardware/software failures and/or disasters. IDC (2010) pointed out that HA is critical to building a strong BC strategy. HA is the foundation of all BC strategies.

- *High reliability* refers to the ability of a server operating environment to minimize (reduce) the occurrence of system failures (both hardware and software related) including some fault-tolerance capabilities. Reliability goals are achieved by using standard redundant components and advanced fault-tolerant solutions (hardware, systems software, application software).
- *High scalability* refers to the ability of a server operating environment of scaling up and out. Servers can be scaled up by adding more processors, RAM, etc., while scaling out means additional computers and forming cluster or grid configurations.

The term "high availability" is associated with high system/application uptime, which is measured in terms of "nines" (e.g., 99.999%). The more nines that represent availability ratio of a specific server, the higher level of availability is provided by that operating platform. According to IDC, HA systems are defined as having 99% or more uptime. IDC (2006, 2009) defined a set of different availability scenarios according to availability ratio, annual downtime, and user tolerance to downtime with regard to several continuous computing technologies that are available today (Table 51.1).

Table 51.2 correlates the number of nines to calendar time equivalents.

All these uptime dimensions can be identified and investigated for several components independently such as server hardware, operating system, application servers, network infrastructure, the whole server environment, or whole information system. Ideas International (IDEAS, www.ideasinternational.com) provides detailed analyses of most widely used server operating platforms with regard to several uptime dimensions.

51.2.2 Impact on Practice

In August 1995, Datamation quoted the results of a survey of 400 large companies that unveiled that "… downtime costs a company $1400 per minute, on average. Based on these figures, 43 hours of downtime per year would cost $3.6 million. One hour of downtime per year amounts to $84,000 per year" (Datamation, 1995). Recounting a situation in which eBay's auction site experienced a serious problem,

TABLE 51.1 IDC Classification of Availability Scenarios

	Availability (%)	Average Annual Downtime	User Tolerance to Downtime
Fault-tolerant continuous availability	99.999	5 min	None
Cluster high availability	99.9	8 h 45 min	Business interruption lost transaction
Stand-alone GP or blade server w/RAID	99.5	43 h 23 min	Tomorrow is okay

Source: IDC White Paper, Reducing downtime and business loss: Addressing business risk with effective technology, IDC, August 2009.

TABLE 51.2 Acceptable Uptime Percentage and Downtime Relationship

Acceptable Uptime Percentage	Downtime per Day	Downtime per Month	Downtime per Year
95	72.00 min	36 h	18.26 days
99	14.40 min	7 h	3.65 days
99.9	86.40 s	43 min	8.77 h
99.99	8.64 s	4 min	52.60 min
99.999	0.86 s	26 s	5.26 min

Source: Adapted from http://technet2.microsoft.com/windowsserver/WSS/en/library/965b2f19-4c88-4e85-af16-32531223aec71033.mspx?mfr=true, November 23, 2011.

a study by Nielsen Media Research and NetRatings Inc. (Dembeck, 1999) describes how the average time spent per person at Yahoo's auction site increased to 18 min on Friday from 7 min on Thursday—the night eBay's site crashed. The number of people using Yahoo's site also skyrocketed to 135,000 on Saturday from 62,000 on Thursday. But the number of users fell to 90,000 on Monday. Financial losses to eBay were estimated at $3–$5 million. Starting from the mid-1990s, there have been several stories and studies on the costs of downtime.

Hiles (2004) estimated that IS downtime put direct losses on brokerage operations at $4.5 million per hour, banking industry $2.1 million per hour, and e-commerce operations $113,000. Fortune 500 companies would have average losses of about $96,000 per hour due to the IS downtime. Nolan and McFarlan (2005) quoted that an attack on Amazon.com would cost the company $600,000 an hour in revenue; they also claimed that if Cisco's systems were down for a day, the company would lose $70 million in revenues.

Another event, primarily based on the lack of scalability, occurred in October 2007 when the Beijing 2008 Olympic Committee started the process of online ticket reservation. The server infrastructure went down immediately after the online reservations and sales were activated. The website for online ticket sales received a couple of million page views with an average of 200,000 ticket requests filed every minute. The system was designed to handle a maximum of one million visits per hour and a maximum of 150,000 ticket requests per minute (Computerworld, 2007).

Martin (2011) cited the results of the study by Emerson Network Power and the Ponemon Institute, which revealed that the average data center downtime event costs $505,500 with the average incident lasting 90 min. Every minute the data center remains down, a company is effectively losing $5600. The study took statistics from 41 U.S. data centers in a range of industries, including financial institutions, health-care companies, and collocation providers.

CA Report (2011) provides the results of an independent research study to explore companies' experiences of IT downtime in which 2000 organizations across North America and Europe were surveyed on how they are affected by IT downtime. The key findings include the following:

- Organizations are collectively losing more than 127 million person hours each year through IT downtime and data recovery with each company losing 545 person hours a year.
- Each business suffers an average of 14 h of downtime per year.
- Organizations lose an average of nine additional hours per year to data recovery time.
- 87% of businesses indicated that failure to recover data would be damaging to the business, and 23% said this would be disastrous.

Fryer (2011) explored some characteristics of several downtime incidents that happened in 2011 such as Verizon's LTE mobile data network outage that lasted several days and Alaska Airlines's server outage in March 2011, which resulted in the cancellation of 15% of the scheduled flights. Neverfail Report (2011) revealed results from a survey of 1473 SME and Enterprise IT professionals in the United States regarding their disaster recovery plans and practices. According to this report,

- Twenty-three percent of respondents have had an IT outage for more than one full business day.
- Hardware and software problems cause most of the IT outages (43% or respondents), while others reported power and datacenter outages (35%), natural disasters (8%), human error (6%), and others (8%).

Forrester conducted a joint research study with Disaster Recovery Journal on most common causes of downtime. In their report (Forrester, 2011, p. 2), they pointed out "Most disasters are still caused by mundane events. That headlining disaster that you're watching out for most likely won't be what causes your downtime—instead, it'll be a backhoe operator at the construction site next door who accidently severs your power or network lines."

All these studies and reports demonstrated the importance of downtime costs and emphasized the need for implementing more advanced availability, scalability, and reliability solutions that may help

in enhancing BC. In addition to technology solutions, several methodologies, methods, and research approaches have been developed over the last decade in order to address these topics in an academic way, not only from technology perspective. In the section that follows, some of these approaches are briefly elaborated.

51.3 Information Architectures: The Downtime Points

Businesses operating in an e-business environment are in most cases run by different forms of business-critical applications. These applications are installed on application servers and accessed by end users over network, often designed or based on the client–server architecture (c/s). Such an architecture consists of one or more servers hosting business-critical applications and a number of clients accessing them. Depending on the server infrastructure's availability, reliability, and scalability, the whole business operates with more or less downtime that, in turn, has more or less impact on its financial performance.

Several models of information architectures have been identified over the last four decades depending mainly on the evolution of hardware and software.

Turban et al. (2005) defined the notion of "information technology architecture" as a high-level map or plan of the information assets in an organization, which guides current operations and is a blueprint for future directions. Jonkers et al. (2006) defined architecture as "structure with a vision," which provides an integrated view of the system being designed and studied. They build their definition on top of a commonly used definition by the IEEE Standard 1471–2000. Versteeg and Bouwman (2006) defined the main elements of a business architecture as business domains within the new paradigm of relations between business strategy and information technologies. Goethals et al. (2006) argued that enterprises are living things, and therefore, they constantly need to be (re)architected in order to achieve the necessary agility, alignment, and integration. Balabko and Wegmann (2006) applied the concepts of system inquiry (systems philosophy, systems theory, systems methodology, and systems application) in the context of an enterprise architecture. Lump et al. (2008) provided an overview of the state-of-the-art architectures for continuous availability concepts as HA clustering on distributed platforms and on the mainframe. Bhatt et al. (2010) considered IT infrastructure as "enabler of organizational responsiveness and competitive advantage."

Today's information systems are mainly based on the three major types of information architecture: legacy–mainframe environment, several models of client–server architectures, and cloud computing-based platforms.

While mostly considered obsolete, the mainframe-based information architecture has been still in use with the redefined role of today's mainframe configurations as servers or hosts within the c/s architecture. Moreover, today's mainframes are used as servers in a cloud-based computing environment. They are known for their HA ratios, e.g., IBM's z systems (www.ibm.com) with the latest versions bringing the redundant array of independent memory (RAIM) technology as a fault-tolerant RAM.

Client–server architectures consist of servers and clients (desktop computers and portable/mobile devices) with applications being installed and running on server computers. Server's side of such architecture is called "business server" or "enterprise server" or, in a broader sense, "server operating environment." It consists of server hardware, server operating system, application servers, and standard server-based and advanced server technologies (also known as "serverware") that are used to enhance key server platform features such as reliability, availability, and scalability. A hybrid architecture is used as well: a combination of mainframe (legacy) platform with newly implemented "thick" or "thin" client–server applications installed on servers.

Enterprise servers running server operating systems are expected to provide an operating environment that must meet much more rigorous requirements than a desktop operating system such as Windows XP or Windows 7 can provide. System uptime that is used as a measure of the availability is one of the most critical requirements.

No matter which of the c/s models is implemented, some most commonly used layers of the client–server architecture can be identified as follows:

- *Client layer*—a layer that is represented by a client application ("thick" or "thin," depending on the type of client–server architecture that is implemented). Each user, from any business unit, department, or business process, uses appropriate client application or web browser over this client layer.
- *Networking layer*—a layer that consists of a number of different data communication devices, data communication media, hardware and software communication protocols, and applications implemented for data communications.
- *Server operating platform layer*—a layer consisting of one or more servers (data, application, web, messaging, firewall, etc.) accompanied by server operating systems and integrated serverware solutions.
- *Data storage layer*—a layer that contains several data storage, data backup, and recovery solutions intended to be used for data storage.

Several modifications of standard c/s architecture are in use today as well in the forms of newly created computing paradigms or models such as web-enabled legacy systems, utility/on-demand computing, software-as-a-service, web-based software agents and services, subscription computing, grid computing, clustering, ubiquitous or pervasive computing, and cloud computing. They are implemented primarily in order to reduce the costs and enhance uptime.

A number of problems that cause downtime may occur within all types of information architectures such as hardware glitches on server components, operating system crashes, network interface card malfunctions, WAN/Internet disconnections, application bugs, system or network administrator's errors, or natural disasters that hit main computer center or cloud computing provider's site (Figures 51.2 and 51.3).

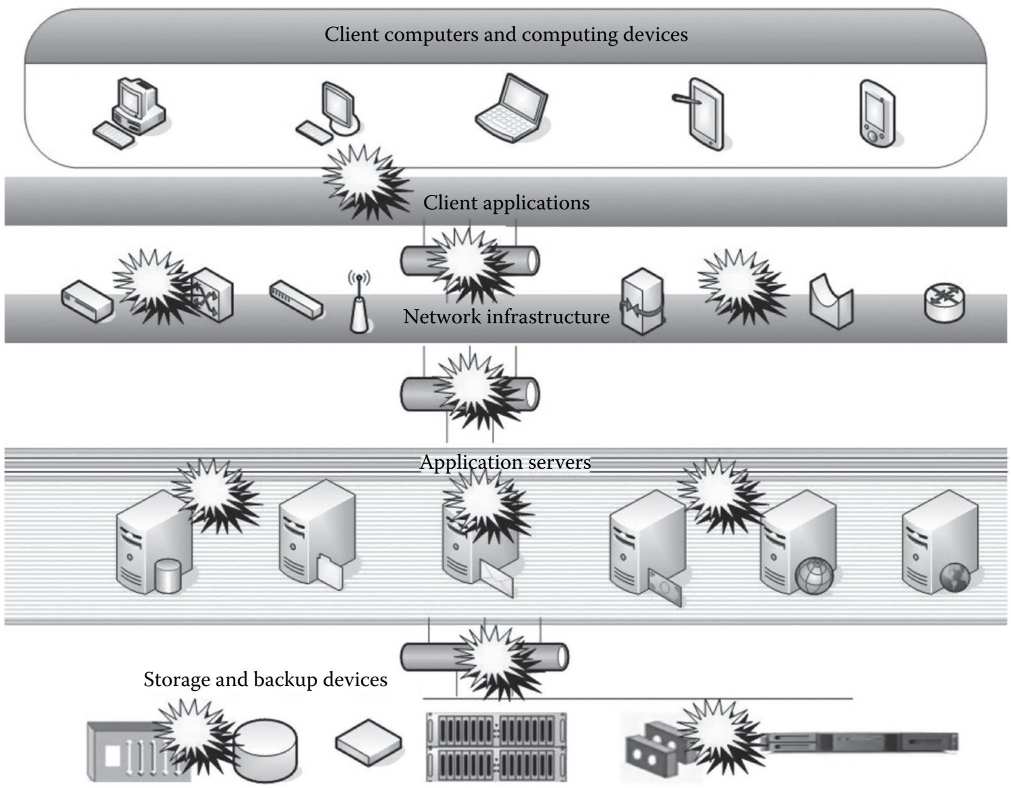

FIGURE 51.2 Downtime points in a client–server architecture.

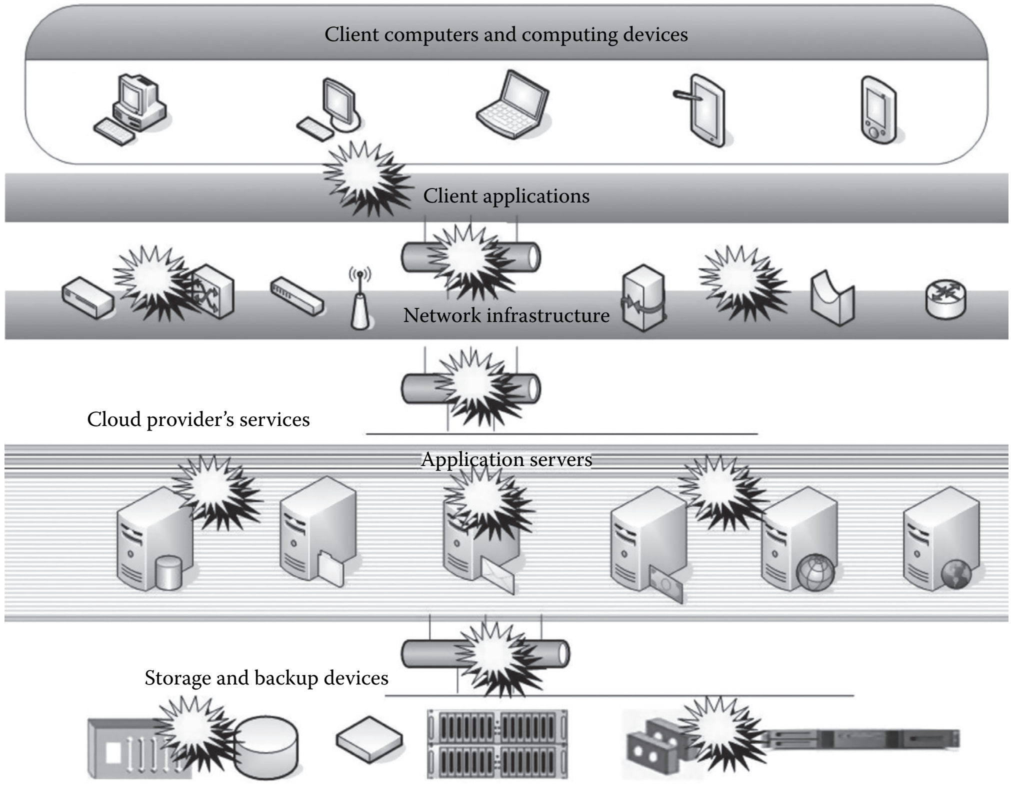

FIGURE 51.3 Downtime points within a cloud-based information architecture.

All these situations may cause unavailability of applications and hence result in a business going "out of business." Therefore, information technologies today play a crucial role by providing several so-called continuous computing technologies that may reduce downtime or enhance the levels of uptime. In all cases, no matter which type of information architecture is used, the server side of the client–server model consisting of one or more application servers plays a crucial role in ensuring the availability of business-critical applications. The downtime points are considered critical in implementing continuous computing solutions for enhancing BC.

Today, cloud computing as a concept tends to replace almost all aforementioned concepts and becomes a platform of choice for many businesses today. Forrester predicts that the global cloud computing market will grow from $40.7 billion in 2011 to more than $241 billion in 2020 (Dignan, 2011). However, the role of servers and server operating environment remains almost the same as business-critical applications are again run by server computers, with the only difference being in the fact that these servers reside within the boundaries of cloud computing provider but not in business's computer center.

Cloud outages such as those of Amazon and Google from April 2011 (Maitland, 2011) showed that even within "by default" highly available infrastructures such as the cloud providers' data centers downtime is still possible and requires attention. In the Amazon's case, huge demand of Lady Gaga fans for the discounted album caused Amazon's servers going down for several hours. In addition, more than 10 h of unavailability of Amazon's servers caused unavailability of some popular websites such as Quora and Reddit. It turned out that these couple of cloud outages could have an impact on the attractiveness of the whole concept of cloud computing (Sisario, 2011).

Cloud requires the same care, skills, and sophisticated management as other areas of IT (Fogarty, 2011). Peiris, Sharma, and Balachandran (2010) developed a Cloud Computing Tipping Point (C2TP) model, which is intended to be used by organizations when deciding between embracing cloud offerings and enhancing their investments in on-premise IT capabilities. Within the model, they list BC and higher uptime as primary attributes for this model. AppNeta revealed recently (Thibodean, 2011) that the overall industry yearly average of uptime for all the cloud service providers monitored by AppNeta is 99.9948%, which is equal to 273 min or 4.6 h of unavailability per year. The best providers were at 99.9994% or 3 min of unavailability a year.

In both standard and web-based client/server and cloud-based architectures, a number of possible problems or critical points can be identified with regard to possible downtime problems:

- Client data-access-related problems on the client PC or client computing devices: hardware, operating system, client applications
- Network infrastructure problems: LAN/WAN/Internet disconnections from servers
- Server operating platform: crashes of server hardware and server operating system
- Data storage: hard disk crash, corrupted file system, magnetic tape broken

As said before, servers can be affected by several types of hardware glitches and failures, system software crashes, application software bugs, hackers' malicious acts, system administrators' mistakes, and natural disasters like floods, fires, earthquakes, hurricanes, or terrorist attacks. Therefore, the process of addressing and managing the IT-related threats has become an important part of managing information resources in any organization. In addition to standard hardware/software failures, some human-related activities can cause system downtime as well.

51.4 Framework for Business Continuity Management

By using Churchman's approach in defining the systemic model (Churchman, 1968, 1971) already applied in explaining information systems for e-business continuance (Bajgoric, 2006), the objective of a continuous computing platform in an organization can be defined as achieving the BC or business resilience. Several information technologies can be applied in the form of continuous computing technologies. This approach leads to identifying the "always-on" enterprise information system that can be defined as an information system with a 100% uptime/zero downtime.

Following Churchman's systemic model, the objective of an "always-on" enterprise information system in an organization can be identified as providing the highest availability, reliability, and scalability ratios for achieving the BC or business resilience. In other words, this refers to the following: continuous data processing with continuous data access and delivery, multiplatform data access, on-time IT services, and better decisions through better data access. Such an information system employs numerous continuous computing information technologies and builds and integrates several components that are aimed at enhancing availability, reliability, and scalability ratios.

A conceptual model used here to illustrate the concepts of BC and continuous computing technologies is given in Figure 51.4.

Continuous computing technologies are considered to be major BC drivers. These technologies include several IT-based solutions that are implemented in order to enhance continuous computing (uptime) ratios such as availability, reliability, and scalability and include the following 10 major technologies:

1. Enterprise servers (server hardware)
2. Server operating systems (server operating environments)
3. Serverware solutions in the form of bundled, in most cases, vendor-specific solutions installed as a set of extensions to standard server operating system
4. Application servers

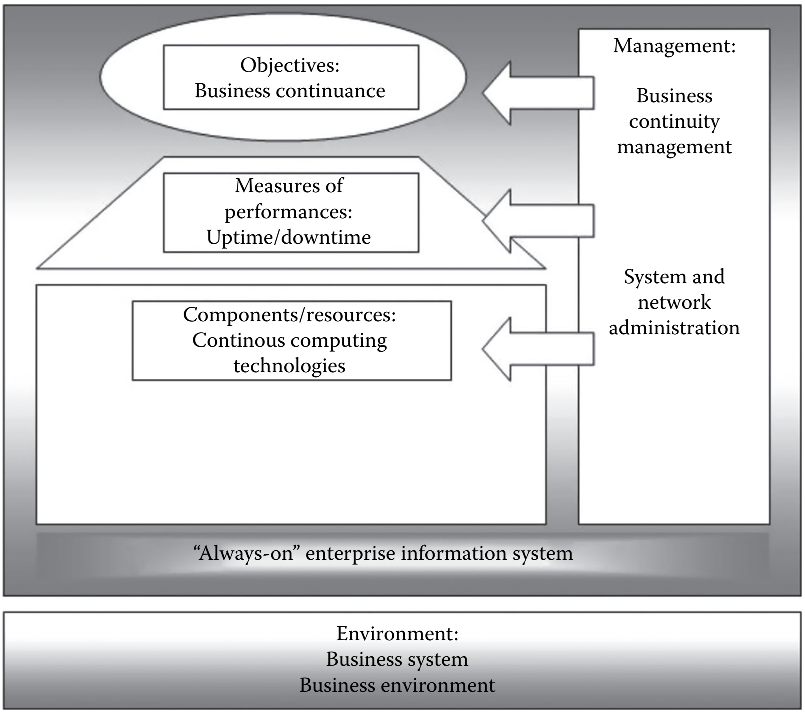

FIGURE 51.4 BC within the systems approach.

5. Server-based fault-tolerance and disaster-tolerance technologies
6. Server clustering
7. Data storage and backup solutions
8. Advanced storage technologies such as mirroring, snapshot, data vaulting
9. Networking and security technologies
10. System administration knowledge and skills

All these technologies are identified as the main building blocks of an always-on enterprise information system. They are represented within the three continuous computing layers as seen in Figure 51.5.

The continuous computing technologies can be implemented within the following three layers:

1. Layer 1—Server and server operating environment
2. Layer 2—Data storage, data backup, and recovery technologies
3. Layer 3—Data communications and security technologies within a networking infrastructure

The first group mainly includes so-called preemptive technologies—standard and specific information technologies and human skills that aim at "preempting" or preventing downtime and keeping system uptime as higher as possible. The second group of continuous computing technologies relate to those solutions that help in recovering from failures and disaster that caused system and application downtime (post-failure). The third group consists of data communications, networking, and security technologies that are used to connect business units and its information system's subsystems and to keep them connected and secure in order to have continuous and secure data access and data exchange. A more detailed depiction of these technologies is given in Figure 51.6 in a revised form of so-called Onion model (Bajgoric, 2010).

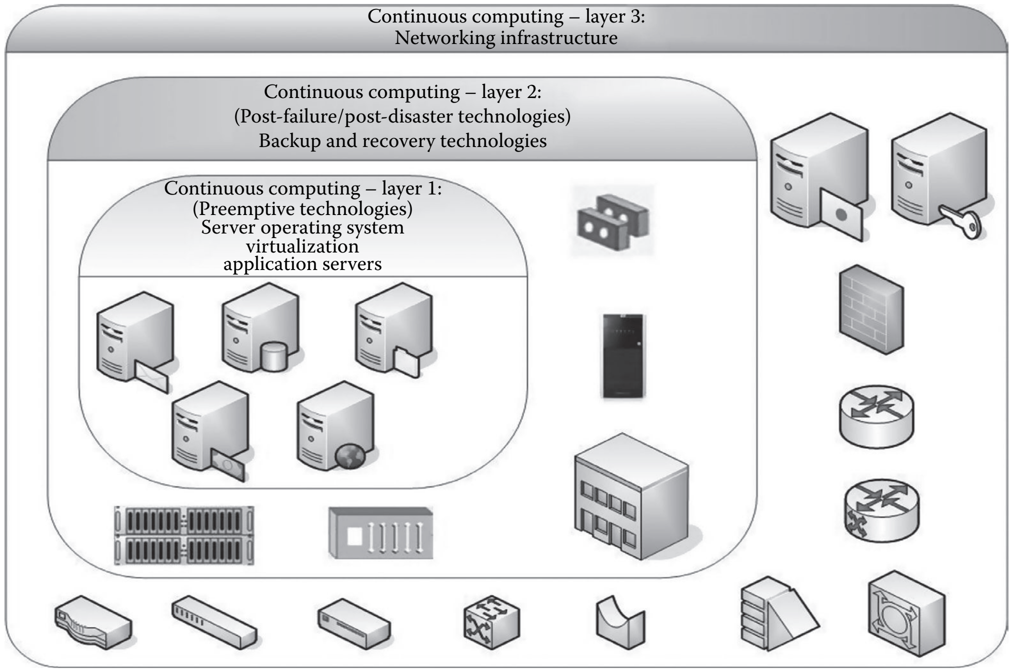

FIGURE 51.5 Three layers of a continuous computing infrastructure for BC.

As can be seen in Figure 51.6, the main technologies that are used to provide HA ratios can be classified into the following categories:

- Server-based technologies
- Server operating systems, enhanced by serverware solutions
- Data storage and backup technologies
- Data communications and networking technologies
- Fault-tolerance and disaster-tolerance technologies
- Redundant units and/or devices such as power supplies and fans, hard disks, network, interface cards, routers, and other communication devices
- Facilities such as UPS units, dual power feeds or generators, and air-conditioning units
- Advanced technologies, such as virtualization, mirroring, snap-shooting, clustering, and data vaulting
- Security and protection technologies
- Predictive system-monitoring capabilities that are aimed at eliminating failures before they occur

Server-based technologies include several types of hardware and software features that support HA technologies such as SMP, clustering, 64-bit computing, storage scalability, RAID and RAIM technologies, fault tolerance, hot spared disk, HA storage systems, online reconfiguration, grid containers, dynamic system domains, virtual machine managers, and hardware and software mirroring. In addition, server platform-based serverware suites include bundled servers, reloadable kernel and online upgrade features, crash-handling technologies, workload management, HA monitors, and Windows/UNIX integration.

Several server operating systems, both commercial proprietary and open source, provide additional HA features. For instance, HP's HP-UX 11.0 server operating platform (http://www.hp.com) provides several HA features such as advanced sys_admin commands (e.g., *fsck, lvcreate, make_recovery, check_recovery*), Veritas's VxFS JFS—Journaled File System, JFS snapshot, dynamic root disk, Bastille, Compartments, fine-grained privileges, role-based access control, and HP Serviceguard. JFS is a recommended file

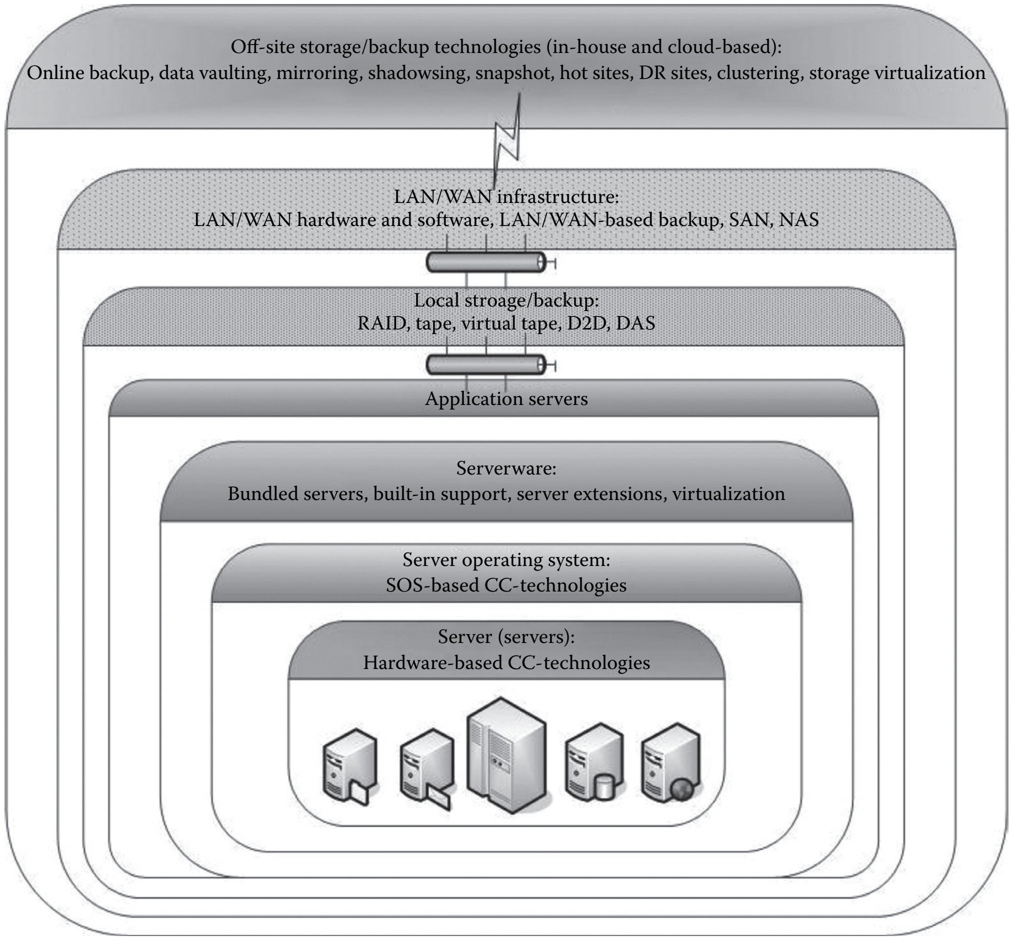

FIGURE 51.6 "Onion" model: unified continuous computing paradigm.

system for high reliability, fast recovery, and online administrative operations. Recently developed new file system by Microsoft for its Windows Server operating system is named the "Resilient File System" (ReFS). It is built on the existing NTFS, enhanced by some additional resiliency features.

Fault-tolerant and disaster-tolerant systems include the following technologies: redundant units, data replication, hot sites, data vaulting, and disaster recovery sites. Some of these technologies overlap with data storage systems, which include standard tape backup technology, Storage Area Networks (SAN), Network Attached Storage (NAS), off-site data protection, Fibre Channel, iSCSI, Serial ATA, etc.

Security and protection technologies that are implemented on computer hardware (servers, desktops, laptops, non-PC computing devices), systems software (restricted use of system privileges, user accounts monitoring, etc.), application software, networking devices such as routers, switches, firewalls, control of network ports, protocols and services, and network applications are also part of unified continuous computing platform shown in Figure 51.6.

The ultimate goal of data communications technologies from BC perspective can be identified as staying connected with employees, customers, and suppliers and ensuring a set of communication technologies to support workforce during disastrous events that interrupt business. These technologies include unified communication technologies that integrate data, e-mail, voice, and video and collaboration

technologies supporting personal productivity software on portable devices, scheduling, web-based collaboration, and content sharing.

The management dimension of the systemic model presented in Figure 51.4 consists of two main aspects of BC management:

1. *Technical aspect* that encompasses system administration activities on operating system and networking levels. Two professional roles responsible for these activities are system and network administrators, respectively.
2. *Managerial aspect* that is characterized by organization-wide efforts to design and implement BC strategies, policies, and activities. BC manager is a person responsible for these tasks. He/she, however, has to work closely with the CIO who is responsible for the whole information technology environment.

System and network administration represent core activities of organizational BC efforts. Technical skills of system administrators or "super-users," and their experience and several "tips and tricks" that they use in administering operating system platforms and computer networks are crucial in maintaining servers and networks up and running on always-on basis. This applies for both preemptive and post-failure operations and activities. Experienced and skilled system/network administrators can significantly improve the levels of system/network uptime while system/network is operational and reduce recovery time in case of system/application or network crashes. The fact that system administrator holds an all-powerful administrative account is a potential risk as well and must be addressed within the managerial scope of organizational BC management.

51.5 Research Issues and Future Directions

This section provides some insights on current works, research issues, and future research directions related to BC. Recent publications are selected and assessed within the following aspects:

- Terminology used
- Frameworks and methodologies
- Business impact
- BC and disaster recovery
- BC and related disciplines such as risk management, auditing, and supply chain management
- IT architectures related

51.5.1 Current Works and Research Issues

From historical perspective, business continuity as a concept has been treated extensively over the last 15–20 years. As already stated in Section 51.2, in the very beginning of the e-business era, Datamation (1995) emphasized the importance of minimizing system downtime. Herbane (2010) noted that business continuity management (BCM) has evolved since 1970s in response to the technical and operational risks that threaten an organization's recovery from hazards and interruptions. Regarding the *terminology*, Broder and Tucker (2012) underlined that BC planning is defined in many different ways reflecting its author's particular slant, background, or experience with the process. They make the difference between the meaning of continuity planning and of a continuity plan. Nollau (2009) introduced the term "enterprise business continuity" and argued that each company should have a functional plan that addresses all processes required to restore technology, an individual responsible for that plan, and a disaster response team at the ready. King (2003) introduced a term "Business Continuity Culture" and underscored the fact that "If you fail to plan, you will be planning to fail." Kadam (2010) introduced the concept of personal BC management.

With regard to *BCP frameworks*, Botha and Von Solms (2004) proposed a cyclic approach to BC planning with each cycle concentrated on a specific BCP goal. Gibb and Buchanan (2006) defined a framework for

the design, implementation, and monitoring of a BC management program within an information strategy. They assign the CIO a key role in both promoting the philosophy of BCM and ensuring that information management incorporates effective plans, procedures, and policies to protect information assets. Gerber and Solms (2005) emphasized the need for a holistic approach that should include a carefully planned security policy, the use of technology, and well-trained staff. They proposed an integrated approach based on analyzing not only risks to tangible assets but also risks to information or intangible assets. Cerullo and Cerullo (2004, p. 71) stated that "… there is no single recommended plan for business continuity; instead, every organization needs to develop a comprehensive BCP based on its unique situation."

Boehman (2009) presented a model for evaluating the performance of a BCM System according to BS 25999 standard. The model calculates the survivability ex-ante if the key performance indicator for the effectiveness exists. Lindstrom et al. (2010) noted that organizations rely too much on the checklists provided in existing BC standards. These checklists for predefined situations need to be created during the BCP process and kept updated in the following maintenance process. They proposed a multi-usable BC planning methodology based on using a staircase or capability maturity model. Herbane, Elliott, and Swartz (2004) examined the organizational antecedents of BCM and developed a conceptual approach to posit that BCM, in actively ensuring operational continuity, has a role in preserving competitive advantage. Walker (2006) considered outsourcing options for BC. Bartel and Rutkowski (2006) proposed a fuzzy decision support system for IT service continuity (ITSC) management. They argued that ITSC management is typically part of a larger BCM program, which expands beyond IT to include all business services within an organization. Brenes et al. (2011) focused on assessing the impact of BC-related governance structures on family business performances. Avery Gomez (2011) underscored the fact that resilience and the continuity of business are factors that rely on sustainable ICT infrastructures. The author presented a model for alignment of BC and sustainable business processes with regard to ICT usage behavior and response readiness. Sapateiro et al. (2011) presented a model of a mobile collaborative tool that may help teams in managing critical computing infrastructures in organizations with regard to BC management.

As for the *business impact*, in addition to what was said in Section 51.2, several authors still emphasize the impacts of downtime on business. According to Stanton (2007, p. 18), "… it can take less than 60 seconds for a company's reputation to be ruined and its business to be crippled. In just one minute, a server failure or hacker can knock out vital applications." He underscored the saying "Fail to Plan, Plan to Fail." Melton and Trahan (2009) argued that critical risks demand critical attention. Vatanasombut et al. (2008) noted that the proliferation of Internet has not only allowed businesses to offer their products and services through web-based applications but also undermined their ability to retain their customers. Ipe et al. (2010) stated that satisfying decision making in public health often stems from the unavailability of critical information from the surveillance environment. They explored the challenges specific to developing and institutionalizing an IT system for emergency preparedness.

Bertrand (2005) researched the relationships between BC and mission-critical applications. He emphasized the role of Replication Point Objective (RPO) and Replication Time Objective (RTO) in recovering from disasters and stressed the role of replication technologies in providing better RPO and RTO values. IDC (2010) pointed out that HA is critical to building a strong BC strategy meaning that HA is the foundation of all BC strategies. Forrester (2009) unveiled that almost 80% of respondents reported that their firms have had to provide proof of BC readiness.

Zobel (2011) defined an analytic approach in representing the relationship between two primary measures of disaster resilience: the initial impact of a disaster and the subsequent time to recovery. Singhal et al. (2010) presented a solution for optimal BC based on the IP SAN storage architecture for enterprise applications used for data management without burdening application server. In order to achieve zero RPO, they proposed introducing a staging server in addition to DR site with replication performances. Lewis and Pickren (2003) pointed out that disaster recovery is receiving increasing attention as firms grow more dependent on uninterrupted information system functioning. Turetken (2008) developed a decision model for locating redundant facilities (IT-backup facility location) within the activities of BC planning. Bielski (2008) stated that some think of BC as doing what is necessary to set up a "shadow"

organization that will take you from incident response through various phases of recovery. Omar et al. (2011) presented a framework for disaster recovery plan based on the Oracle's DataGuard solution that includes remote site, data replication, and standby database.

Pitt and Goyal (2004) saw BCM as a tool for facilities management. They argued that both FM and BCP are important on strategic level and pointed out the need for the involvement of facilities manager in BC planning. Yeh (2005) identified the factors affecting continuity of cooperative electronic supply chain relationships with empirical case of the Taiwanese motor industry. Wu et al. (2004) identified continuity as the most important behavioral factor on business process integration in SCM. Hepenstal and Campbell (2007) provided some insights on transforming Intel's worldwide Materials organization from crisis management and response to a more mature BC approach. According to these authors, the BC-oriented approach improved Intel's ability to quickly recover from a supply chain outage and restoring supply to manufacturing and other operations. Craighead et al. (2007) considered BC issues within the supply chain mitigation capabilities and supply chain disruption severity. They proposed a multiple-source empirical research method and presented six propositions that relate the severity of supply chain disruptions. Tan and Takakuwa (2011) demonstrated how the computer-based simulation technique could be utilized in order to establish the BC plan for a factory. Blackhurst et al. (2011) provided a framework that can be used to assess the level of resiliency and a supply resiliency matrix that can be utilized to classify supply chains according to the level of resiliency realized. Kim and Cha (2012) presented the improved scenario-based security risk analysis method that can create SRA reports using threat scenario templates and manage security risk directly in information systems. Greening and Rutherford (2011) proposed a conceptual framework based on network theories to ensure BC in the context of a supply network disruption. Lavastre et al. (2012) introduced the term supply chain continuity planning framework within the concept of supply chain risk management (SCRM).

Wan (2009) argued that in current business-aligned IT operations, the continuity plan needs to be integrated with ITSC management if an organization is going to be able to manage fault realization and return to normal business operations. He proposed the framework based on using the IT service management portal and network system-monitoring tool. Winkler et al. (2010) focused on the relationships between BCM and business process modeling. They proposed a model-driven framework for BCM that integrates business process modeling and IT management. Kuhn and Sutton (2010) explored the alternative architectures for continuous auditing by focusing on identifying the strengths and weaknesses of each architectural form of ERP implementation.

According to IDC's white paper (2009), by adopting industry best practices (e.g., ITIL, CobIT) and updating their IT infrastructure, companies can lower annual downtime by up to 85%, greatly reducing interruptions to daily data processing and access, supporting BC, and containing operational costs. Umar (2005) explored the role of several business servers in designing an IT infrastructure for "next-generation enterprises." Butler and Gray (2006) underscored the question on how system reliability translates into reliable organizational performance. They identify the paradox of "relying on complex systems composed of unreliable components for reliable outcomes." Adeshiyan et al. (2010) stated that traditional high-availability and disaster recovery solutions require proprietary hardware, complex configurations, application specific logic, highly skilled personnel, and a rigorous and lengthy testing process.

Williamson (2007) found that in BC planning, financial organizations are ahead of other types of businesses. Kadlec (2010) reported on the IT DR planning practices of 154 banks in the United States. Arduini and Morabito (2010) argued that the financial sector sees BC not only as a technical or risk management issue but also as a driver toward any discussion on mergers and acquisitions. Sharif and Irani (2010) emphasized HA, failover, and BC planning in maintaining high levels of performance and service availability of eGovernment services and infrastructure.

51.5.2 Summary of Recent Publications

Table 51.3 provides a summary of recent publications published over the last 10 years about BC, BC management, and related topics. They are listed with regard to research focus and main contribution.

TABLE 51.3 Review of Literature Related to Business Continuity

Article Year	Authors	Research Focus/Main Contribution
2003	Lewis and Pickren	Presented a technique that can be used to assess the relative risk for different causes of IT disruptions
2003	King	Introduced a term "Business Continuity Culture." Underscored the fact "If you fail to plan, you will be planning to fail"
2004	Botha and Von Solms	Proposed a BCP methodology that is scalable for small and medium organizations. Developed a software prototype using this cyclic approach and applied it to a case study
2004	Herbane et al.	Examined the organizational antecedents of BCM and developed a conceptual approach to posit that BCM, in actively ensuring operational continuity, has a role in preserving competitive advantage
2004	Finch	Revealed that large companies' exposure to risk increased by interorganizational networking and that having SMEs as partners in the SCM further increased the risk exposure
2004	Wu et al.	Identified continuity as the most important behavioral factor on business process integration in SCM
2004	Pitt and Goyal	Considered BCM as a tool for facilities management
2004	Cerullo and Cerullo	Provided guidelines for developing and improving a firm's BCP consisting of three components: a business impact analysis, a DCRP, and a training and testing component
2005	Bertrand	Estimated the relationships between BC and mission-critical applications. Emphasized the role of RPO and RTO in recovering from disasters and stressed the role of replication technologies
2005	Yeh	Identified the factors affecting continuity of cooperative electronic supply chain relationships with empirical case of the Taiwanese motor industry
2005	Gerber and Solms	Suggested the need for a holistic approach that should include a carefully planned security policy, the use of technology, and well-trained staff. The article indicated how information security requirements could be established
2005	Umar	Investigated the role of several business servers in designing an IT infrastructure for "next-generation enterprises"
2006	Walker	Considered outsourcing options for BC
2006	Bartel and Rutkowski	Argued that ITSC management is typically part of a larger BCM program, which expands beyond IT to include all business services. Proposed a fuzzy decision support system for ITSC management
2006	Butler and Gray	Underscored the question on how system reliability translates into reliable organizational performance. Identified the paradox of "relying on complex systems composed of unreliable components for reliable outcomes"
2006	Gibb and Buchanan	Defined a framework for the design, implementation, and monitoring of a BC management program within an information strategy
2007	Williamson	Found that in BC planning, financial organizations are ahead of other types of businesses
2007	Hepenstal and Campbell	Provided some insights on transforming Intel's worldwide Materials organization from crisis management and response to a more mature BC approach
2007	Craighead et al.	Proposed a multiple-source empirical research method and presented six propositions that relate the severity of supply chain disruptions
2008	Vatanasombut et al.	Argued that the proliferation of Internet has not only allowed businesses to offer their products and services through web-based applications but also undermined their ability to retain their customers
2008	Bielski	Stated that some think of BC as doing what is necessary to set up a "shadow" organization that will take you from incident response through various phases of recovery

TABLE 51.3 (continued) Review of Literature Related to Business Continuity

Article Year	Authors	Research Focus/Main Contribution
2008	Turetken	Developed a decision model for locating redundant facilities (IT-backup facility location) within the activities of BC planning
2008	Lump et al.	Investigated several aspects and relationships among HA, disaster recovery, and BC solutions
2009	Wan	Argued that in current business-aligned IT operations, the continuity plan needs to be integrated with ITSC management
2009	Boehman	Presented a model for evaluating the performance of a BCM System according to BS 25999 standard. The model calculates the survivability ex-ante if the key performance indicator for the effectiveness exists
2009	Nollau	Introduced the term "enterprise business continuity"
2010	Adeshiyan et al.	Stated that traditional high-availability and disaster recovery solutions require proprietary hardware, complex configurations, application-specific logic, highly skilled personnel, and a rigorous and lengthy testing process
2010	Ipe et al.	Stated that satisfying decision making in public health often stems from the unavailability of critical information from the surveillance environment. They explored the challenges specific to developing and institutionalizing an IT system for emergency preparedness
2010	Singhal et al.	Presented a solution for optimal BC based on the IP SAN storage architecture for enterprise applications used for data management without burdening application server
2010	Kuhn and Sutton	Explored the alternative architectures for continuous auditing by focusing on identifying the strengths and weaknesses of each architectural form of ERP implementation
2010	Tammineedi	Categorized the key BCM tasks into three phases of BC: pre-event preparation, event management, and post-event continuity. The Business Continuity Maturity Model of Virtual Corporation presented as a tool
2010	Lindstrom et al.	Proposed a multi-usable BC planning methodology based on using a staircase or capability maturity model
2010	Kadlec	Reported on the IT DR planning practices of 154 banks in the United States
2010	Arduini and Morabito	Argued that the financial sector sees BC not only as a technical or risk management issue but also as a driver toward any discussion on mergers and acquisitions. The BC approach should be a business-wide approach and not an IT-focused one
2010	Winkler et al.	Focused on the relationships between BCM and business process modeling. Proposed a model-driven framework for BCM that integrates business process modeling and IT management
2010	Kadam	Introduced the concept of personal BC management
2011	Tan and Takakuwa	Demonstrated how the computer-based simulation technique could be utilized in order to establish the BC plan for a factory
2011	Zobel	Presented an analytic approach in representing the relationship between two primary measures of disaster resilience: the initial impact of a disaster and the subsequent time to recovery
2011	Omar et al.	Presented a framework for disaster recovery plan based on the Oracle's DataGuard solution that includes remote site, data replication, and standby database
2011	Greening and Rutherford	Proposed a conceptual framework based on network theories to ensure BC in the context of a supply network disruption
2011	Brenes et al.	Focused on assessing the impact of BC-related governance structures on family business performances
2011	Avery Gomez	Presented a model for alignment of BC and sustainable business processes with regard to ICT usage behavior and response readiness

TABLE 51.3 (continued) Review of Literature Related to Business Continuity

Article Year	Authors	Research Focus/Main Contribution
2011	Sapateiro et al.	Designed a mobile collaborative tool that helps teams managing critical computing infrastructures in organizations. Developed a data model and tool supporting the collaborative update of Situation Matrixes
2011	Blackhurst et al.	Provided a framework that can be used to assess the level of resiliency and a supply resiliency matrix that can be utilized to classify supply chains according to the level of resiliency realized
2012	Broder and Tucker	Made the difference between the meaning of continuity planning and of a continuity plan
2012	Lavastre et al.	Considered BC planning within the "supply chain continuity planning framework." Introduced the concept of Supply Chain Risk Management (SCRM)
2012	Kim and Cha	Presented the improved scenario-based security risk analysis method, which can create SRA reports using threat scenario templates and manage security risk directly in information systems

51.5.3 Future Research Directions

Future research directions with regard to BC can be identified around the following research topics:

- Integrating BC management, IT management, and organizational management
- Positioning BC as part of business risk management
- Exploring relations between BC management and disaster recovery management
- Developing and implementing advanced server technologies for enhancing servers' availability, reliability, and scalability
- Developing frameworks for organization-wide implementation of BC
- Implementing several information technologies as BC drivers
- BC and IT/IS security
- BC and information resources management
- BC and system and network administration
- BC in cloud computing environment
- HRM dimensions of BC management: the roles of system and network administrators, BC managers, IT managers, CIOs, and CSOs
- Implementing BC within the compliance regulations, legislations, and standards on BCM

Given the fact that several terms and buzzwords related to BC have been introduced over the last decade, it would of interest to further explore and develop theoretical aspects and practical implications of those terms such as business continuity, business continuance, business resilience, always-on business, zero-latency business, always-available enterprise, and so on.

51.6 Conclusions

Modern business owes a lot to information technology. It is well known that information technologies provide numerous opportunities for businesses in their efforts to reduce the costs, increase the profits, enhance the quality of products and services, improve relations with customers, and cope with increasing competition. At the same time, modern businesses face several situations in which they may suffer due to some IT-related problems that cause lost data, data unavailability, or data exposed to competition. In addition, some businesses experienced so-called IT-based horror stories due to bad implementations of enterprise information systems.

With advances in e-business, the need for achieving "a near 100%" level of business computing availability was brought up yet again. Consequently, the term "business continuity management" was coined up and became a significant part of organizational information management. BCM has become an integral

part of both IT management and organizational management. It involves several measures (activities) that need to be implemented in order to achieve higher levels of the system/application availability, reliability, and scalability ratios. BC relies on several continuous computing technologies that provide an efficient and effective operating environment for continuous computing. Implementation of continuous computing technologies provides a platform for "keeping business in business." Therefore, an enterprise information system should be managed from BC perspective in a way that this process includes both managerial and system administration activities related to managing the integration of BC drivers.

In this paper, an attempt was made to explore the concept of business continuity from both managerial and IT perspective. In addition, several illustrations of downtime costs are provided in order to demonstrate the importance of BC for modern business.

Technical Foundations of Information Systems Security

Daniela Oliveira
Bowdoin College

Jedidiah Crandall
University of New Mexico

52.1 Introduction

This chapter provides an overview on information systems security. It starts by discussing the key concepts and underlying principles of computer security, common types of threats and attacks, and the origins of software vulnerabilities.

The chapter then reviews UNIX-like security abstractions: the hierarchy of processes in a system, hardware support for separating processes, the UNIX file system hierarchy, and authentication. Then it is shown how these protections extend to the network, how a typical TCP/IP connection is protected on the Internet, and how web servers and browsers use such protections. Security flaws are also covered with a detailed discussion of the most dangerous software vulnerabilities: buffer overflows and memory corruption, SQL injection, cross-site scripting (XSS), and time-to-check-time-to-use race conditions. Following this, the chapter argues that all the vulnerabilities cross multiple layers of abstraction (application, compiler, operating systems (OSes), and architecture) and discusses research directions to mitigate this challenge and better protect information systems.

52.2 What Is Computer Security?

Computer security addresses policies and mechanisms to protect automated computer systems so that the confidentiality, integrity, and availability of their resources are protected. These resources can be software (the OS and application programs), firmware, hardware, information and data (e.g., a file

system), and all networked communication between two end systems [34]. The three pillars upon which computer security is based (confidentiality, integrity, and availability) are commonly referred in the literature by the CIA acronym [10,51].

Confidentiality requires that private, confidential, or sensitive information and system resources are not disclosed to unauthorized parties. This can be achieved through access control or encryption. Access control policies manage the access to the system and its resources and have two main functions: authentication and authorization. Authentication is the process that determines the identity of someone attempting to access a system or a set of data [27]. This assessment of the individual or any other entity (e.g., another system) is usually done through credentials, such as a password, fingerprint, or a card. Authorization is the process that determines the set of resources or data a person or a third-party entity (once authenticated) are allowed to access. For example, once authenticated in a certain Linux machine, user `bob` has access to all files located in his home directory, but he may not have access to the files located in user `alice`'s home directory.

Integrity requires that data or a system itself is altered only in an authorized manner. It is usually described as a two-concept definition: data integrity and system integrity [34]. Data integrity requires that information and programs are changed only in a specified and authorized manner. System integrity requires that a system functions free from any unauthorized change or manipulation.

Availability requires that a system works in a timely manner and its resources and data are promptly available to authorized users.

52.2.1 Vulnerabilities, Threats, Attacks, and Countermeasures

A vulnerability is an error or a weakness in the design or implementation of a system that could be exploited to violate its security policy. Software systems cannot be guaranteed to be free from vulnerabilities because designers and programmers make mistakes, and current verification and testing techniques cannot assure that a significantly complex piece of software meets its specification in the presence of errors or bad inputs. The likelihood of a successful exploitation of a vulnerability depends on its degree and the intelligence of the exploitation. A threat is a potential for violation of security caused by the existence of vulnerabilities. A threat might never be realized, but the fact that it exists requires that measures should be taken to protect the system against this potential danger. An attack is a threat that was realized or a concrete exploitation of a system vulnerability. We call the agent that performed such malicious actions the *attacker*. An attack is active when it attempts to alter system resources and affect its operations, and it is passive when it attempts to learn or leverage system information without affecting its operation or assets [49].

A countermeasure is any procedure taken to reduce a threat, a vulnerability, or an attack by eliminating or preventing it, or minimizing the harm it can cause by discovering, stopping, or reporting it so that some recovery action is taken [49]. Countermeasures can be classified into three types: preventive, detective, and corrective. A preventive countermeasure prevents an attack from happening in the first place. For example, the use of a password prevents non-authorized users to access a system, and network filters prevent known malicious packets from being processed by the network stack at the OS. A detective countermeasure accepts that an attack may occur, but is able to determine when a system is under compromise and possibly stop the attack or at least warn a system administrator. This usually involves the monitoring of several system attributes. After an attack occurs, a corrective countermeasure (usually the hardest to implement) tries to bring the system back to a stable error-free state, for example, by restoring a file system with backup data.

52.2.2 Origins of Current Vulnerabilities

Even though information systems will never be immune to errors, it is important to understand how the interplay of different layers of abstraction exacerbates the problem. Consider the simplest security model: a gatekeeper. An analogy to the gatekeeper model is the bank teller. Suppose a bank customer

needs to use a bank service or access their account. They will walk up to the bank teller's window and give them instructions about what they would like to be done (e.g., withdraw money, deposit, transfer, or obtain a cashier's check). The bank teller is a trusted entity that actually carries out these actions on behalf of the customer, while at the same time, ensuring that the bank's policies are being followed. For example, in the case of money withdrawal, the bank policy is to never give out money to a customer before subtracting the same amount from their account.

This abstraction represents the gatekeeper concept from an early OS called MULTICS [17,21]. In MULTICS, processes were separated into several rings, and the lower the ring number some code is executing in, the greater its privileges are. The system must be aware of ring crossing at the architecture layer. When code in ring *i* attempts to transfer control to code in ring *j*, for the code in ring *j* to do something on its behalf, a fault occurs and control is given to the OS. The gatekeeper is the software abstraction that handles this fault. Its name originates from the view of crossing rings as crossing walls separating them. Ideally the gatekeeper should be as simple as possible. Simplicity allows for ease of inspection, testing, and verification. The design is streamlined and the likelihood of an error is reduced. On the other hand, if the gatekeeper is complex, involving a set of abstractions where many high-level, more complex abstractions are built on top of simpler, lower-level ones in multiple tiers, the possibility of introduction of an avenue for deceiving the gatekeeper is greatly increased.

Most modern information systems are based on what can be called UNIX-like systems (including Windows-based systems). These systems combine memory separation of different processes with a hierarchical file system and process hierarchy to achieve security. These systems are designed with complex and cross-layered security abstractions. For example, for security reasons, a process can access memory only inside its address space. However, the implementation of the abstraction of functions uses the process address space (the stack region) at user level. The stack region should be under strict OS control, but processes have access to their address space. Further, sensitive low-level control information (a function return pointer) belonging to the architecture level (value of the program counter register) can be accessed by the OS and processes because it is stored on the stack.

Furthermore, the application of certain security principles can add to the complexity of the gatekeeper and even conflict with one another. In a classic and much-referenced paper from 1975, Saltzer and Schroeder [43] described several design principles, provided by experience, for the design of information systems and security mechanisms.

One of these principles is *fail-safe defaults*. It states that the design of a system or a security mechanism should be very conservative regarding access to objects and functionalities. The default situation should be lack of access, and the security mechanism should identify which subjects should be allowed access and under which circumstances. The intuition behind this principle is that an error in the security mechanism design will fail by restricting access, and this situation would be easily identified by those subjects (a user, program, or another system) who should be granted access to the system. The alternative design, whose default situation is complete access with access control decisions based on exclusion of rights, will fail by allowing access to a subject that should not receive it. Examples of the application of this principle would be to enforce that only well-typed programs are loaded into memory as processes, or to only allow access to memory locations until they are explicitly the right type that the access is meant for. These examples conflict with the principle of *economy of mechanism* that states that the design of a secure system or security mechanism should be as simple and as small as possible. UNIX-like systems give each process its own address space and several ways to communicate with other processes. Each process is responsible for the accesses it makes to its own memory, which errs more on the side of the second principle.

52.2.3 Why Is Securing a System Hard?

There are many reasons that make computer security a challenge. First, as we have mentioned before, systems will never be vulnerability-free because they are becoming more and more complex and

diverse and are devised by humans, who are likely to introduce flaws into the system. Another challenge is that the problem of checking if a piece of code contains malicious logic is undecidable [10]. Malware detectors usually target a particular type of attack and may present false positives and false negatives. Also computer security is an arms race between attackers and security researchers and engineers. Unfortunately, the attackers have the edge because their goal is much simpler than those of a security researcher: an attacker needs to find a suitable vulnerability and exploit it; a security engineer must address all types of vulnerabilities a system may have and patch them while avoiding the introduction of new vulnerabilities in the process. Further, we have been witnessing an increase in the complexity of malware and attackers. The current generation of attackers is extremely creative, financially and politically motivated, and structured much like any well-operated criminal organization [1]. Traditional security models and solutions have difficulty keeping up with these attackers' level of innovation and ingenuity. Finally, many systems are not (or were not) designed with security as a requirement. In many cases, security is an afterthought and sometimes is perceived as an inconvenience or a burden, for example, decreasing performance, increasing costs, and making systems harder to operate.

52.3 UNIX-Like Security Abstractions

In this section, we will build a UNIX-like system from the ground up conceptually, to see what the different protection mechanisms are and how they interact with each other through many layers of abstraction.

The protection mechanisms that form the foundation of a UNIX-like system can be divided into two types: *reference-checking* and *reference-omitting*. Reference-checking mechanisms use an access control list to check all accesses to an object to see if the subject trying to access the object has permission to perform that kind of access, where the access could be an operation such as read, write, or execute. Reference-checking mechanisms associate with each object a list of the accesses that various subjects can perform on that object. Reference-omitting mechanisms only give a reference that can be used to make an access to subjects that have permission to make that access, so that every access need not be checked. In other words, every subject is associated with a list of objects that it can access. Note that the references given to a subject to refer to a subject must be protected themselves for reference-omitting mechanisms, however. Reference-omitting mechanisms are often referred to as capabilities and reference-checking as access control lists, but in this section, we will avoid these names to avoid confusion and historical connotations.

An example of a reference-omitting mechanism is a page table. Page table mappings have bits to allow write access, for example, but there is no notion of different processes in these access controls. The mechanism that stops one process from accessing the physical memory of another process is that it has no virtual-to-physical mapping in its page table for the physical page frames of the other process. So it is not a matter of an access control check based on distinguishing one process from another, but rather the process that is not supposed to access the memory has no possible way to calculate or forge a virtual address that refers to the physical memory of the other process. The reference is omitted, rather than checked.

52.3.1 Hardware Support

First, what do we mean by a "UNIX-like" system? We mean a system that combines memory separation of different processes with a hierarchical file system and process hierarchy to enable security. Although we will not discuss Microsoft Windows in this section, under this definition, Windows is a UNIX-like system. Windows has a rich set of security features [42], but the foundations of security in Windows are still based on the abstractions of processes and files that UNIX pioneered. UNIX owes

many of its security ideas to MULTICS [44,17]. In MULTICS, processes were separated by segmentations and organized into 64 rings, with inner-more rings having more privileges. A process could only request for higher-privileged processes to do tasks on their behalf by going through a gatekeeper that initiated code defined at a higher privilege, which had the effect of restricting the interaction between the two processes based on this code that resided in an inner-more ring. The code itself would reason about what it should or should not do on behalf of the lower-privileged process with respect to security. UNIX reduced this idea down to two rings, with the kernel in the inner ring and user space processes in the outer ring, and with the processes themselves being kept separate by a different mechanism.

To support the abstractions of UNIX-like security mechanisms, all that is required of the hardware is a mechanism to separate these two rings and then a different mechanism to separate the processes. For modern UNIX-like systems, a supervisor bit that distinguishes kernel mode from user mode is enough for a ring abstraction where there are only two rings. Most modern CPUs that have support for OSes have a bit that indicates when the CPU is in supervisor mode vs. user mode. The exact mechanism varies, but the effect is the same. In the MIPS instruction set architecture, for example, this bit is implied by the virtual address. The x86 architecture provides four rings, but typical UNIX-like system use only two of them (the inner-most and the outer-most) [13].

Not every system is based on UNIX-like abstractions, but UNIX-like abstractions have proven to be very portable. Eros [48] is an OS that is radically different from UNIX in terms of security abstractions and uses all four rings of the x86. Eros is considered a capability-based system. Levy [29] describes historical systems that were based on the notion of capabilities and required much more elaborate hardware for OS security support than is required by UNIX. In fact, for many secure system designs that are not UNIX-like, the hardware and the OS are codesigned for each other, which can limit portability and requires careful thought about the security abstractions whenever two different systems interact.

UNIX-like security mechanisms also need some way for processes to be kept separate. Specifically, one process should not be able to read from or write to other process's memory without such permission being explicitly granted. Originally, UNIX used the PDP-7's segmentation mechanism to separate the memory address spaces of processes. Segmentation divides physical memory into contiguous segments that can be referenced with a base and offset. Because processes could not change their base and the bounds of their offsets are checked, processes cannot access the other segments in memory. Because of external fragmentation, however, paging is now much preferred to segmentation as a way to separate processes' address spaces in physical memory. As discussed earlier, paging is a reference-omitting mechanism, in which processes are given only virtual address mappings in their page tables for those physical memory page frames that they are allowed to access. In this way, there is no way for the process to calculate a virtual address pointer that references the memory of another process unless such a reference is placed in the page table of that process by the OS kernel.

52.3.2 Security Abstractions Implemented in Software

Once the hardware has provided the OS with the two important protection mechanisms that we have now discussed (one to separate the kernel from user space and another to separate processes within user space), kernel data structures can be built to support security at higher levels of abstraction. Individual processes can interact with other processes or with the kernel only through explicit requests to the kernel called system calls (similar to MULTICS's gatekeeper mechanism). Only the kernel has the privileges necessary to directly access system resources such as the network, hard drive, keyboard, and monitor. In this way, the kernel can separate these resources into different files for different users, different network connections, etc., and enforce access controls.

A UNIX-like system uses two key data structures as the basis for security: file system access controls and the process hierarchy. A typical UNIX-like system has different users that must authenticate to the

system and then a special user called *root* that can override most access controls. Users own processes, and they also can own file system objects. File system objects can be actual files, network sockets, other interprocess communications mechanisms, special character devices, or anything that processes can interact with through a file abstraction.

The most basic access controls are those on actual files on the file system, for example,

```
-rw-r-----   1   johndoe   faculty   179    2011-11-12   17:35   myfile.txt
drwxr-xr-x   6   johndoe   johndoe   4096   2011-11-12   18:48   Mydirectory
-rwxr-xr-x   1   johndoe   johndoe   253    2011-11-21   10:37   myprogram.pl
```

In this example, the user johndoe can read from or write to `myfile.txt`, and any user in the faculty group can read from this same file, but other users cannot. Anyone is allowed to enter the `mydirectory` directory and list the files there because of the global read and execute permissions (assuming they are already able to reach this point in the directory structure), and anybody can read and execute the executable program `myprogram.pl`. UNIX-style file permissions are a reference-checking mechanism; consequently, all attempts to add a file to a process's file descriptor table must be checked.

It is important to note that these access controls are checked for *processes* owned by users, and they are typically checked only at the time the file is opened. Processes can have any number of files opened for reading or writing at one time, and these are placed in a file descriptor table so that the process can refer to files in system calls to the kernel by the number of the file descriptor entry. The file descriptor table is a reference-omitting mechanism; once a file is placed in the file descriptor table for a certain type of access, the process can perform that access on the file without any additional checks.

In UNIX-like systems, there is a special process called a *shell* that prompts a user for commands and allows the user to cause the system to do a wide range of actions. A typical user shell process in a UNIX-like system has access to tools such as compilers that allow it to basically do arbitrary computations and any sequence of system calls desired. *Thus, the security of a UNIX-like system is based not on what a user process cannot do within its own address space, but on restricting how it interacts with other processes.*

This leads to the hierarchy of processes. *This hierarchy is not necessarily a privilege hierarchy where parents always have more privileges than their children*. This is a very important point, because prevention of privilege escalation and interacting with remote users from around the world over the network in a secure way are both based on limiting the influence that one process can have over another.

UNIX processes can use the `fork()` system call to create new children below them in the hierarchy. These children typically inherit all of the parent's open file descriptors as well as the parent's *real user ID* and *effective user ID*. The parent can also pass arguments to the child. The real user ID is what the ID of the actual user who initiated the process is, while the effective user ID is the one that actually is checked for controlling access to files and other system resources. Typically, these IDs are the same, but they can be different when the child uses the `execve()` system call to mount a binary with the *setuid bit* set, for example,

```
-rwsr-xr-x 1 root root 36864 2011-02-14 15:11/bin/su
```

The "s" in the permissions indicates that the setuid bit is set for this binary program file. This bit means that any process that mounts this binary (mounting means that the old executable code along with the rest of the address space of the process is discarded in memory and the process is now running the binary code in `/bin/su`) has their effective user ID set to the owner of the file, in this case root, rather than the process that executed it. For example, *passwd* is a UNIX utility for changing passwords that has the setuid bit set. This means that when user *bob* invoked this utility, the process runs with effective user id set to *root*, instead of *bob*, which is necessary since only root has permissions to write to the `/etc/passwd` file to update bob's password.

The `execve()` system call is used for mounting new binaries. Most binaries do not have the setuid bit set, so that the child still has the same effective user ID of the parent. Binaries such as `/bin/su`, which is used to change to another user and possibly the `root` user by entering that user's password,

need the effective permissions of root to read the password file and authenticate a new user and then create a shell process for the new user.

Now we have built a conceptual picture that will help to understand the exploits in Section 52.4. The hierarchy of processes comes from parents who `fork()` children and then those children sometimes `execve()` to run other binaries. The parents can pass arguments and open file descriptors to the children. The children may sometimes have higher privileges than the parent by mounting setuid binaries. The root of the tree is typically the `init` process, which forks `login` children that run as root but can read users' usernames and passwords and fork children that become *shell* processes after dropping their permissions to the appropriate level for that user. So we have a hierarchy of processes, where lower privileged processes can have ancestors, siblings, and descendants with a higher privilege level than themselves and where there are many ways for processes to communicate through files, sockets, pipes, and other mechanisms.

The major thing missing from this conceptual picture is the network. It is possible for a process on one system to open a network socket to a remote system that is treated by both processes the same as any other entry in their file descriptor table. For example, a web browser on one system can request a remote socket with a web server on another system, and if the kernels of these two systems allow this access and successfully do a three-way TCP handshake, the processes can now communicate over the network.

What we will see in Section 52.4 is that when processes can communicate with one another one process can influence the actions of the other through software vulnerabilities and then subvert security mechanisms.

52.4 Vulnerabilities and Countermeasures

In this section, we discuss several common and dangerous vulnerabilities or security flaws that allow attackers to target user-level programs and OSes. The context here is that each of these vulnerabilities allows attackers to violate the assumptions upon which the security abstractions of a UNIX-like system are built.

52.4.1 Buffer Overflows

This vulnerability is one of the most common and dangerous security flaws and was first widely publicized by the Morris Internet Worm in 1988 [2], which compromised thousands of machines and caused millions of dollars in losses.

A buffer is a memory area in which contiguous data (an array or a string) can be stored. A buffer overflow is the condition at an interface under which more data are placed into a particular finite size buffer than the capacity allocated [35]. This location could hold other program or system variables and data structures, function pointers, or important program control information such as a function return address.

To understand buffer overflows, it is important to review how a program is laid out in memory by the OS for execution. The process address space or the memory region that can be accessed by the process is divided into four main regions. The code region is read-only, fixed-sized, and contains the program machine code. The data area is also fixed-sized and contains global and static variables and data structures used by the program. The heap is used for dynamic allocation of program variables and data structures. The stack is used to implement the abstraction of function calls. It grows toward the lower memory addresses of a process and stores function's local variables, parameters, and also control information such as a function return address.

Consider the code snippet illustrated in Figure 52.1. Upon calling *b*, *a* pushes the parameters for *b* on the stack in reverse order of declaration. The return address of *a* (the next instruction that should continue to be executed when *b* returns) is also saved on the stack. Then the address of *a*'s stack frame pointer is saved on the stack. This is necessary to recover it after function *b* returns. Notice that *b*'s local

```
Void a() {
       int x = 1;
       int y = 2;
       b(x,y);
}

Void b(int x, int y) {
       char buff[8];
       int a;
       a = x + y;
          ...
}
```

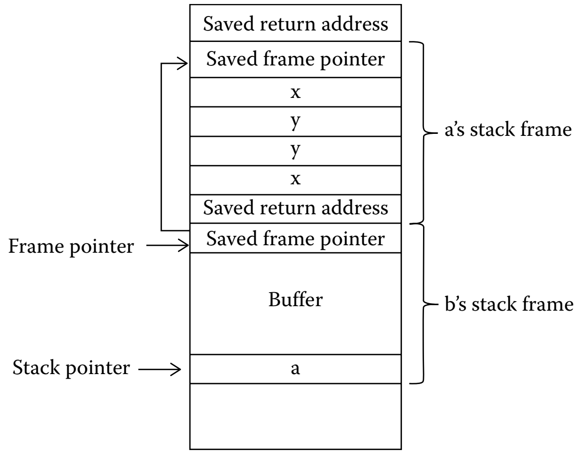

FIGURE 52.1 Function invocation.

variables (including the vulnerable buffer) are stored below the saved value of the frame pointer and the return address. Also when an input is stored in a buffer, the bytes are placed toward higher addresses in the process address space, i.e., toward the saved frame pointer and return address.

A stack-based buffer overflow can cause several types of harm in a system or program. An unintentional buffer overflow may cause a program or an OS to terminate or crash, due to the corruption of data structures, stack frame pointer, or return address. For example, if the return address is overwritten with a random value, this value will be loaded into the PC register (called the *program counter,* which contains the address of the next instruction to be executed by the CPU), and the CPU might identify this value as an illegal memory access (possibly outside the process address space). A malicious buffer overflow will occur when the attacker carefully crafts an input where the return address is overwritten with an address chosen by the attacker. This address could be within the malicious input string and points to malicious instructions that open a *shell* (a command-line interface to the OS), giving the attacker administrator privileges in the system if the compromised program is privileged. The malicious address could also correspond to a library function (e.g., libc) allowing the attacker to perform malicious actions by combining existing functions (also called *return-to-libc* attack [31]).

52.4.1.1 Defenses

There are several different proposed solutions currently in use against buffer overflow attacks, and they can be broadly classified into two types: compile-time and run-time [30].

A compile-time solution involves adding code to programs with the goal of preventing and detecting buffer overflows. Type-safe languages such as Java and Python have the compiler generate code to check array bounds, thus preventing such attacks. The StackGuard gcc extension [15] protects the stack by inserting additional instructions to a function entry and exit code. The goal is to protect the stack by checking if it is corrupted. A function entry code writes a canary value (named after the miner's canary used to detect poisonous air in a mine and warn the miners) below the saved frame pointer on the stack. Upon exiting, the function exit code checks that the canary was not corrupted, as the attacker will need to corrupt the canary to tamper with the return address. This canary value must be randomly generated to avoid the possibility of an attacker guessing the value and overwriting it with the proper value during the attack, thus evading detection.

Run-time solutions protect vulnerable programs by detecting and stopping buffer overflow attacks during execution. One common approach is to protect the address space of a process against improper execution. A buffer overflow attack usually causes a control flow change that leads to the execution of malicious instructions that are part of the malicious input string in the stack. If the stack is marked

as nonexecutable, many instances of buffer overflow attacks can be stopped. The assumption is that executable code is supposed to be located in the code portion of a process address space and not on the stack, heap, or data areas. The Solar Designer's StackPatch [18] modifies the address space of a process to make the stack non-executable. The $W \otimes X$ defense [55] ensures that no memory location in a process address space can be marked both as writable (W) and executable (X) at the same time. Most OSes now offer such protection. While this type of defense is considered an effective protection mechanism that is relatively simple to implement, there are situations where a program must place executable code in the stack [51]: just in time compilers (Java), implementation of nested functions in C, and signal handlers.

Another approach is address space randomization. In order to exploit a buffer overflow, an attacker needs to predict the location of a return address or know the exact location of a library function. Randomly arranging the memory positions of key areas such as the heap, stack, and libraries makes this prediction harder for the attacker. This idea is implemented in PAX ASLR [39] and is supported by many OSes.

52.4.2 Vulnerabilities and UNIX-Like Abstractions

Buffer overflows demonstrate an important part of UNIX-like security abstractions, which is that the code that a process runs and the semantics of the program are a key part of the security of a system. In UNIX-like systems, a setuid root binary such as {\tt su} must carefully process all of its inputs to make sure that the terminal it inherited from its parent must provide a valid username and password before a shell for entering commands as the new user is created as its child. Similarly, a web server must check the inputs it receives on a network socket from a remote client to make sure it is a valid request within the HyperText Transfer Protocol (HTTP) protocol and then must only carry out the actions necessary to provide the HTTP service as per that protocol. Since "change the root password on the system" is not part of the HTTP protocol, the remote client cannot directly subvert security within the confines of the protocol. Rather, within the confines of UNIX-like security abstractions, attackers exploit vulnerabilities to have more influence on other processes than the security model for the system allows.

This notion of processes acting on other processes' behalf (perhaps remotely) leads to three kinds of exploits for vulnerabilities: those that directly corrupt a process and take it over through communication, those that confuse other processes at higher levels of abstraction, and those that attack the communication channel between two processes to exploit a trust relationship between them.

52.4.2.1 Directly Corrupting a Process and Taking It Over

Control flow hijacking attacks communicate with other processes in a malicious way that causes that process to effectively be taken over so that its computations and system calls are now controlled by the attacker.

The most famous example of this kind of attack is the buffer overflow, which was explained earlier in this section. These are a special case of a broader problem known as memory corruption attacks and that includes not only buffer overflows [6], but also format string attacks [46] and double `free()'s` [7]. By corrupting the memory of another process through malicious inputs that it cannot handle properly, it is possible to inject the attacker's own instructions to be executed by that process. This can be used to elevate privileges on the current system by corrupting another process with higher privileges, which might be a child with the setuid bit set. This can also be used to take control of a remote machine by corrupting one of its processes. This can be achieved by, for example, connecting to a web server that has a memory corruption vulnerability in its implementation. It can also be achieved by, for example, sending a user a malicious file through e-mail such as a PDF that exploits a software bug in their PDF reader. Mitigations for buffer overflow attacks were discussed earlier in this section.

In these previous examples, a process owned by the attacker sent malicious inputs to another process, either on the same system or on a remote system over the network, where the other process has privileges that the attacker needs in order to subvert security. Another example of directly taking over

a process is SQL injection. A typical SQL injection attack involves at least three processes that communicate remotely over the network. The attacker's remote client process sends form inputs to a web server process, which embeds these inputs into an SQL query to interact with a database. The attacker uses SQL delimiters in their form inputs to change the boundaries between the SQL code and their inputs. In this way, they can control the SQL code that the SQL server executes.

For example, web server code might read `$name` and `$password` from a web client and then build an SQL query for a database server using the following substitution:

```
SELECT * FROM users WHERE name = '$name' and password = '$password'
```

The single quote (') is a special delimiter in the SQL language. The attacker can leave the password blank and enter this as their username:

```
'; DROP TABLE users--comment…
```

This causes the SQL server to execute the following SQL code that it receives from the web server, with the effect of the entire table of users in the database being deleted:

```
SELECT* FROM users WHERE name =''; DROP TABLE
users-- comment…
```

Fundamentally, SQL injection vulnerabilities are a problem where the inputs from the attacker span across more than a leaf in the parse tree of the resulting query [52]. For example, the name "`bob`" would be a single leaf in a parse tree of the SQL language for the resulting query, but the name "`'; DROP TABLE users -- comment…`" will be a tree itself with "`;`", "`DROP`", "`TABLE`", "`users`", and "`--comment`" all being separate leaves in the tree. Su and Wassermann [52] describe a dynamic approach to detect SQL injection exploits.

XSS is another type of vulnerability where information being passed between more than two processes leads to the ability for the attacker to control another process via malicious inputs. In the case of XSS, a typical XSS attack allows one web client to pass scripted code to another client through the server. For example, suppose a forum on a web server allows users to add HyperText Markup Language (HTML) to their forum comments so that other users can see formatted text with tags, such as bold text, for example, **This is a bold forum comment**. Suppose also that the forum server does a poor job of filtering out HTML code that could harm other clients, such as Javascript:

```
body onload = " alert('xss')"
```

This is a real example from a college campus course content management system [26] that allows students and faculty to post HTML-formatted messages in forums or as e-mail. An HTML blacklist is applied to not allow HTML tags that lead to the execution of Javascript, but the blacklist only filters out well-formed HTML (in this case well-formed HTML would have a closing angle bracket, ">") while most browsers will execute the Javascript code `alert('xss')` even without well-formed HTML. In this example, if a student posts this string or sends it as an e-mail to the instructor, the message recipient will receive a pop-up window that simply says, "xss". The ability to execute arbitrary Javascript could, however, give students the ability to cause the instructor's web browser to update the gradebook or do any action that the instructor's browser session has the privileges to perform. For a good explanation of XSS vulnerabilities and why blacklist approaches fail, as well as a dynamic approach that is sound and precise so that XSS vulnerabilities can be removed from source code at development time, see Wassermann and Su [59].

52.4.2.2 Confusing Other Processes at a Higher Level of Abstraction

It is also possible to confuse other processes at a higher level of abstraction, so that the process violates security on the attacker's process behalf of even if the vulnerable process is not corrupted to the point where the attacker has complete control.

An example of this would be a Time of Check to Time of Use (TOCTTOU) race condition vulnerability. This kind of vulnerability occurs when privileged processes are provided with some mechanism to check whether a lower-privileged process should be allowed to access an object before the privileged process does so on the lower-privileged process's behalf. If the object or its attribute can change between this check and the actual access that the privileged process makes, attackers can exploit this fact to cause privileged processes to make accesses on their behalf that subvert security.

The classic example of TOCTTOU is the sequence of system calls of `access()` followed by `open()`. The `access()` system call was introduced to UNIX systems as a way for privileged processes (particularly those with an effective user ID of root) to check if the user who owned the process that invoked them (the real user ID) has permissions on a file before the privileged process accesses the file on the real user ID's behalf. For example,

```
if (access("/home/bob/symlink", R_OK | W_OK) ! = -1)
{
          //Symbolic link can change here
          f = fopen("/home/bob/symlink", "rw");
          …
}
```

What makes this is a vulnerability is the fact that the invoker of the privileged process can cause a race condition where something about the file system changes in between the call to `access()` and the call to `open()`. For example, the file `/home/bob/symlink` can be a symbolic link that points to a file the attacker is allowed to access during the `access()` check but is changed to point to a different file that needs elevated privileges for access. The attacker can usually win this race by causing the `open()` system call to block for a hard drive access to read one of the directory entries (for more details see Borisov et al. [12]). The only effective way to mitigate TOCTTOU vulnerabilities is to identify sequences of system calls that are unsafe with respect to concurrency and not use them in privileged code. For example, secure code should never use `access()` followed by `open()`, which means that the `access()` system call has fallen into disuse since predicating file opens was its purpose.

52.4.2.3 Attacking the Communication Channel between Two Processes

Directly corrupting another process or confusing it at a higher level of abstraction typically entails one process sending malicious inputs to another that the receiving process cannot handle correctly with respect to security due to a bug. It is also possible for malicious agents on the network to corrupt the communication channel between two processes. When two processes communicate over the Internet, there is typically some trust relationship implied, such as that a web browser trusts that it is communicating with the web server a user intended to contact when it passes the user's username and password along on the network. Network attacks seek to exploit this trust relationship.

Network attacks and the security mechanisms to thwart them are too numerous to discuss thoroughly here. For discussion of the most salient attacks on the most common protocols, see Tews et al. [56] regarding Address Resolution Protocol (ARP) injection and Wired Equivalent Privacy (WEP) attacks, Qian and Mao [41] regarding TCP hijacking, Savage et al. [45] regarding a large-scale attack on TCP congestion control, Karlin et al. [25] regarding attacks on Border Gateway Protocol (BGP) routing, and Wright [61] regarding an attack on Domain Name System (DNS).

We will use a typical HTTP connection with a typical network stack to illustrate the different possible points of attack. If a user wants to go to http://www.example.com, the first step is to find an IP address for this URL. The user's system is configured to use a specific DNS server for this lookup, which is typically the DNS server for their organization or Internet Service Provider. But before the DNS server can

be contacted by IP address, the user's system must find an ARP address for either the DNS server or a gateway router that can reach the DNS server. ARP is a typical layer 2 protocol of the OSI model [40], and layer 1 is the physical layer.

Above ARP is the IP layer, layer 3. This allows packets to be routed, for example, to the DNS server and back. The user's system makes a DNS request and the DNS server returns the IP address for http://www.example.com. Now the user uses the TCP protocol (layer 4) on top of IP routing to connect to the remote machine where the process for the web server that hosts http://www.example.com is running. The web browser and web server can now communicate through an interprocess communication mechanism called a socket using a layer 7 (application layer) protocol that they have agreed on, in this case HTTP.

Disclosure, deception, disruption, and usurpation [49] are possible at all of these layers. For ARP, any machine on the local network can answer for any IP address, even the gateway. At the IP layer, any of the routers that any packets for the connection go through have arbitrary control over that packet, and attacks on the routing system such as BGP attacks [25] mean that attackers can ensure that certain connections will be routed through their routers. Higher layers can also be attacked, for example, responses to DNS requests can be forged. Because of all of these possible attacks, an important protocol for securing interprocess communication over the Internet in an end-to-end fashion with public key cryptography is Secure Sockets Layer (SSL) at layer 6 (the presentation layer). Using a public key infrastructure (PKI), typically the Certificate Authority (CA) system for the Internet, it is possible for two remote processes to set up an encrypted channel between them. Because SSL is a layer 6 protocol that is implemented in libraries, applications can still communicate with a socket Inter-Process Communication (IPC) mechanism, with the SSL library performing the encryption and decryption relatively transparently. The encryption is end-to-end, meaning that it provides a level of privacy, integrity, and authentication that mitigates many network-based attacks.

In summary, UNIX-like systems start from very simple hardware protections that prevent processes from directly accessing blocks of data on the hard drive or gaining raw access to the network card to interfere with others' network connections. They then build many layers of abstraction on top of this. Process hierarchies, file system hierarchies, network protocols such as ARP, TCP/IP, DNS, and BGP, and many other abstractions build a bridge between the hardware's simple notion of security and the security properties that human users expect for higher-level concepts like URLs (e.g., http://www.example.com). Software bugs called vulnerabilities make it possible for attackers to violate the assumptions that these layers of abstraction are built upon.

52.5 Vulnerabilities and Layers of Abstraction

In this section, we discuss how security vulnerabilities in computer systems cross multiple layers of abstraction (application, compiler, OS, and architecture). This cross-layer existence not only makes the problem of classifying vulnerabilities hard but also hinders the development of strong and flexible solutions to remove or mitigate them.

52.5.1 Challenge of Classifying Vulnerabilities

Bishop and Bailey [11] have analyzed many vulnerability taxonomies and showed that they are imperfect because, depending on the layer of abstraction a vulnerability is being considered, it can be classified into multiple ways.

A taxonomy is a classification system that allows a concept (e.g., a vulnerability) to be uniquely classified. The RISOS [3], the Protection Analysis [24], Landwehr et al. [28], and Aslam [8] taxonomies represented important studies to help systems designers and administrators to understand vulnerabilities and better protect computer systems. The Protection Analysis study [24], for instance, sought to understand OS security vulnerabilities and also identify automatable techniques for detecting them. Bishop and

Bailey [11] also summarized Peter Neumann's presentation of this study [32] with 10 classes of security flaws (which are further summarized here).

1. Improper protection domain initialization and enforcement: vulnerabilities related to the initialization of a system and its programs and the enforcement of the security requirements.
   a. Improper choice of initial protection domain: vulnerabilities related to an initial incorrect assignment of privileges.
   b. Improper isolation of implementation detail: vulnerabilities that allow users to bypass a layer of abstraction (e.g., the OS or the architecture) and write directly into protected data structures or memory areas, for instance, I/O memory and CPU registers.
   c. Improper change: vulnerabilities that allow an unprivileged subject to change the binding of a name or a pointer to a sensitive object so that it can bypass system permissions.
   d. Improper naming: vulnerabilities that allow two objects to have the same name, causing a user to possibly execute or access the wrong object. For example, if two hosts have the same IP address, messages destined to one host might arrive at another one.
2. Improper validation: vulnerabilities related to improper checking of operands or function parameters.
3. Improper synchronization: vulnerabilities arising when a process fails to coordinate concurrent activities that might access a shared resource.
   a. Improper indivisibility: interruption of a sequence of instructions that should execute atomically.
   b. Improper sequencing: failure to properly order concurrent read and write operations on a shared resource.
4. Improper choice of operand and operation: vulnerabilities caused by a wrong choice of the function needed to be called from a process. For example, a cryptographic key generator invoking a weak pseudorandom number generator.

Bishop and Bailey [11] showed how this study and others [3,8,24,28] fail to uniquely identify vulnerabilities using two very common and dangerous security flaws as examples: buffer overflows (described here as an example) and TOCTTOU.

52.5.1.1 Nonunique Classification of Buffer Overflows

At the application layer, this vulnerability can be classified as type 2 (improper validation) because the flaw was caused by the lack of array bounds checking by the programming language compiler and also by the program itself. From the perspective of the subject (in this case the attacker process) who used the vulnerable program, the flaw can be classified as type 4 (improper choice of operand) as the string passed as a parameter was too long (overflowed the buffer at the vulnerable process).

At the OS layer, the vulnerability can be classified as 1b (improper isolation of implementation detail). In this case, the vulnerable process was able to bypass OS controls and overwrite an area of the process address space corresponding to a function return address.

We can also argue that at the architecture layer, this vulnerability can be classified as 1b (improper isolation of implementation detail) as the compromised process was also able to directly write into the PC register. When a function returns, the return address (which was maliciously overwritten) is written into the PC register and the program control flow jumps to that location. It can also be classified as 1c (improper change) as the value of the PC register was maliciously changed.

52.6 Research Issues

Protecting an OS kernel against vulnerabilities is a difficult problem given the complexity and variety of its code. Many proposed solutions employ virtualization. In the traditional virtual machine (VM) usage model [14], it is assumed that the VM is trustworthy and the OS running on top of it can be easily

compromised by malware. This traditional usage model comes with a cost: the semantic gap problem. There is a significant difference between the abstractions observed by the guest OS (high-level semantic information) and by the VM (lower-level semantic information). These solutions use introspection to extract meaningful information from the system they monitor/protect [20]. With introspection, the physical memory of the current VM instance is inspected and high-level information is obtained by using detailed knowledge of the OS algorithms and data structures. Another line of research [36] employs active collaboration between a VM and a guest OS to bridge the semantic gap. In this approach, a guest OS running on top of a VM layer is aware of virtualization and exchanges information with the VM through a protected interface to achieve better security. A sizable amount of research is being pursued toward building secure web browsers [9,22,54,58]. We have been witnessing a shift to a web-based paradigm where a user accomplishes most of their computing needs using just a web browser [57]. Original browsers were designed to render static web pages, but as web applications and dynamic content became common, many attackers explored weaknesses in the design of these browsers (e.g., XSS and memory exploitation) to launch attacks. Researchers now view browsers as OSes and are investigating new models where browsers are designed by having their components isolated using the process abstraction, which can contain or prevent web-based vulnerabilities.

Return-oriented programming is a relatively new type of attack [47] inspired by the return-to-lib-c approach of exploiting the stack. The attacker does not inject foreign malicious code but instead combines a large number of short instruction sequences (called gadgets) that return and transfer control to another gadget. Several gadgets crafted from legitimate libraries, OS code, or program instructions can be used to perform malicious computations. This type of attack is dangerous because it does not involve foreign code and can evade important defense approaches such as $W \otimes X$. Current research focuses on randomizing or rewriting code so as to prevent an attacker from finding useful gadgets in them [23,38]. Randomization as a way to thwart attacks is a promising idea that dates back to 1997 [19], but there still is no widely accepted methodology for determining how much more difficult randomization makes it for the attacker to develop exploits for any given vulnerability.

The mitigations discussed for each vulnerability in Section 52.2.2 are specific to one type of vulnerability. Another approach to secure systems is to provide processes with security mechanisms that allow for finer-grained separation. These mechanisms are largely based on Saltzer and Schroeder's Principle of Least Privilege, and the security comes from the fact that when processes are corrupted by an attacker, the attacker is more limited if those processes have very limited privileges. SELinux [4] and Linux capabilities [13] are examples that have already been fully integrated into a modern OS. Capsicum [60] is an example of an effort that is still in the research phase.

Many attempts have been made to secure commodity code without making major changes to it (such as separating it into different privilege domains). One notable effort is dynamic information flow tracking (DIFT) [16,33,53]. DIFT systems have proven effective at detecting existing attacks in full systems without compromising on compatibility, but cannot make any guarantee about attacks designed for DIFT systems. This is because tracking information flow dynamically is difficult to do precisely enough for programs that make heavy use of memory indirections such as pointers and control structures such as `for` loops [5,50].

52.7 Summary

This chapter discussed the foundations for security in information systems, which are based on the triad of confidentiality, integrity, and availability. We can find the origins of many software security flaws in the intertwinement of different layers of abstraction (application, compiler, OS, and architecture), which hinders the development of simple but strong protection mechanisms for information systems and their resources. Nearly all information systems run on UNIX-like OSes (where Windows-based systems are also included). Knowledge about how such OSes are designed allows us to understand their different protection mechanisms, how the hardware facilitates their security, and also their most common types

of vulnerabilities and associated countermeasures. The challenge of countering and even classifying vulnerabilities can also be traced to the fact that they cross multiple layers of abstraction.

Given that security vulnerabilities involve more than one layer of abstraction, defending against them should involve some form of collaboration between layers of abstraction to bridge their semantic gap. Current security solutions operate at one particular level of abstraction. For example, they operate at the application level as a user-level process [37], at the compiler level so that safer binary code is generated [15], at the system level as an OS security extension [4], and also at the architecture level, usually involving a VM layer [20]. Multiple-tiered and collaborative security approaches seem a promising research direction to mitigate these vulnerabilities.

53.1 Introduction

In the last few years, the wide availability of computational and storage resources at low prices has substantially changed the way in which data are managed, stored, and disseminated. As testified by the growing success of data outsourcing, cloud computing, and services for sharing personal information (e.g., Flickr, YouTube, Facebook), both individuals and companies are more and more resorting to external third parties for the management, storage, and (possibly selective) dissemination of their data. This practice has several advantages with respect to the in-house management of the data. First, the data owner needs neither to buy expensive hardware and software licenses nor to hire skilled personnel for managing her data, thus having economic advantages. Second, the external server guarantees high data availability and highly effective disaster protection. Third, even private individuals can take advantage of the avant-garde hardware and software resources made available by providers to store, elaborate, and widely disseminate large data collections (e.g., multimedia files). The main problem of this outsourcing trend is that the data owner loses control over her data, thus increasing security and privacy risks. Indeed, the data stored at an external server may include sensitive information that the external server (or users accessing them) is not allowed to read. The specific security and privacy issues that need to be considered vary depending on the main goal for which the data owner provides her data to a third party. In particular, we identify two scenarios: a *data outsourcing* scenario where the data owner delegates the management and storage of a data collection, possibly including sensitive information that can be selectively accessed by authorized users, to a *honest-but-curious* external server; and a *data publishing* scenario where the data owner delegates the storage of a data collection to an external

server for its public dissemination. An honest-but-curious server is typically trusted to properly manage the data and make them available when needed, but it may not be trusted by the data owner to read data content. Both these scenarios are characterized by the interactions among four parties: *data owner*, an organization (or an individual) who outsources her data to an external server; *user*, an individual who can access the data; *client*, the user's front-end in charge of translating access requests formulated by the user in equivalent requests operating on the outsourced data; and *server*, the external third party that stores and manages the data.

The goal of this chapter is to provide an overview of the main data security and privacy issues that characterize the two scenarios mentioned previously along with possible approaches for their solution (Sections 53.2 and 53.3). For each problem considered, we also briefly mention some open issues that still need further consideration and analysis. Clearly, since the data outsourcing and data publishing scenarios have some similarities, we also describe the main issues that are common to the two scenarios (Section 53.4). In the discussion, for simplicity, but without loss of generality, we assume that the outsourced data are stored in a single relation r, defined over relational schema R $(a_1,\ldots,a_n)$, which includes all sensitive information that needs to be protected. The problems as well as the approaches for their solution that we will describe in the following can however be applied to any data model (e.g., XML data or arbitrary set of resources).

53.2 Security Issues in the Data Outsourcing Scenario

The security issues specifically characterizing the data outsourcing scenario are related to three main problems that will be discussed in the following: (1) data confidentiality, (2) efficient evaluation of users' queries at the server side, and (3) access control enforcement.

53.2.1 Data Confidentiality

Collected data often include sensitive information whose protection is mandatory, as also testified by recent regulations forcing organizations to provide privacy guarantees when storing, processing, or sharing their data with others (e.g., [9,59,60]). Since in the data outsourcing scenario these data are not under the direct control of their owners, individuals as well as companies require the protection of their sensitive information not only against external users breaking into the system, but also against malicious insiders, including the storing server. In many cases, the storing server is assumed to be *honest-but-curious*, that is, it is relied upon for ensuring availability of data but it is not allowed to read their content. Ensuring effective and practical data protection in this scenario is complex and requires the design of approaches allowing data owners to specify privacy requirements on data, as well as techniques for enforcing them.

Solutions: The first approach proposed to provide confidentiality of outsourced data consists in wrapping a protective layer of encryption around sensitive data to counteract both outside attacks and the curiosity of the server itself (e.g., [10,36,39,63]).

Encryption represents an effective approach to guarantee proper confidentiality protection. However, since the server is not authorized to decrypt outsourced data, it cannot evaluate users' queries. To minimize the use of encryption and make access to outsourced data more efficient, recent proposals combine *fragmentation* and *encryption* techniques [1,14,15]. These approaches are based on the observation that often data are not sensitive per se but what is sensitive is their association with other data. It is therefore sufficient to protect sensitive associations to preserve data confidentiality. The privacy requirements charactering the outsourced data collection are modeled through *confidentiality constraints* [1]. A confidentiality constraint c over a relational schema $R(a_1,\ldots,a_n)$ is a subset of attributes in R, meaning that for each tuple in r, the (joint) visibility of the values of the attributes in c is considered sensitive and must be protected. As an example, Figure 53.1b illustrates a set of five confidentiality constraints for relation PATIENTS in Figure 53.1a, stating that the list of Social Security

Patients							
<u>SSN</u>	Name	DoB	ZIP	Race	Disease	Doctor	
123456789	Alice	1980/02/10	22010	Asian	Flu	I. Smith	c_1={SSN}
234567891	Bob	1980/02/15	22018	Asian	Gastritis	J. Taylor	c_2={Name, Disease}
345678912	Carol	1980/04/15	22043	Asian	Flu	K. Doe	c_3={Name, Doctor}
456789123	David	1980/06/18	22040	White	Hypertension	L. Green	c_4={DoB, ZIP, Race}
567891234	Erik	1980/06/18	22043	White	Asthma	K. Doe	c_5={Disease, Doctor}
678912345	Frank	1980/10/07	22015	White	HIV	L. Green	
789123456	Gary	1980/10/15	22010	White	HIV	L. Green	
891234567	Hellen	1980/10/28	22018	Black	Flu	I. Smith	
(a)							(b)

FIGURE 53.1 An example of relation (a) and of a set of constraints over it (b).

Numbers is considered sensitive (c_1); the associations of patients' names with the diseases they suffer from or their caring doctor are considered sensitive (c_2 and c_3); the association among date of birth, ZIP, and race is considered sensitive (c_4); and the association between the disease of a patient and her caring doctor is considered sensitive (c_5).

Given a relation *r* and a set C of confidentiality constraints over it, the goal is to outsource the content of *r* in such a way to obfuscate sensitive associations. The idea is to encrypt the sensitive attributes by making them non-intelligible to non-authorized users, and to break sensitive associations by partitioning the attributes in *R* in different subsets (fragments) that cannot be joined by non-authorized users. A fragmentation correctly enforces the confidentiality constraints if no fragment stored at the external server represents all the attributes in a constraint in clear form.

The approaches proposed in the literature combining fragmentation and encryption to protect data confidentiality differ in how the original relational schema *R* is fragmented and in how and whether encryption is used. In particular, existing approaches can be classified as follows.

- *Noncommunicating pair of servers* [1]: *R* is partitioned into two fragments stored at two non-communicating servers. Encryption is used to protect attributes that cannot be stored at any of the two servers without violating constraints. For instance, consider relation Patients in Figure 53.1a and the confidentiality constraints in Figure 53.1b. A correct fragmentation is represented by F_1 = {<u>`tid`</u>, `Name`, `DoB`, `ZIP`, `SSN`^{k}, `Doctor`^{k}}, F_2 = {<u>`tid`</u>, `Race`, `Disease`, `SSN`^{k}, `Doctor`^{k}}, where F_1 is stored at the first server and F_2 is stored at the second server. Attribute `tid` is the tuple identifier, introduced in both fragments to guarantee the lossless joint between F_1 and F_2. Attributes `SSN`^{k} and `Doctor`^{k} contain the encrypted version of attributes `SSN` and `Doctor`, respectively.
- *Multiple fragments* [15]: *R* is partitioned into an arbitrary number of disjoint fragments (i.e., with no common attribute), possibly stored at a same server. Each fragment includes a subset of the original attributes in the clear form and all the other attributes in encrypted form. For instance, consider relation Patients in Figure 53.1a and the confidentiality constraints in Figure 53.1b. A correct fragmentation is represented by F_1 = {<u>`salt`</u>, `Name`, `DoB`, `ZIP`, `enc`}; F_2 = {<u>`salt`</u>, `Race`, `Disease`, `enc`}; and F_3 = {<u>`salt`</u>, `Doctor`, `enc`} in Table 53.1. Here, `salt` is a randomly chosen value different for each tuple in each fragment, and `enc` is the result of the encryption of the attributes in Patients not appearing in the clear in the fragment, concatenated with the salt.
- *Departing from encryption* [14]: *R* is partitioned into two fragments, one stored at the data owner side and one stored at the server side, which can be joined by authorized users only. For instance, consider relation Patients in Figure 53.1a and the confidentiality constraints in Figure 53.1b.

TABLE 53.1 An Example of Correct Fragmentation in the Multiple Fragments Scenario

A correct fragmentation is represented by F_o = {`tid`, `SSN`, `Name`, `Race`, `Disease`}, stored at the data owner side; and F_s = {`tid`, `DoB`, `ZIP`, `Doctor`}, stored at the storing server side. Note that F_o can include in the clear all the attributes composing a constraint since it is stored at a trusted party.

Open issues: Different open issues still remain to be addressed to effectively and efficiently provide confidentiality of outsourced data. For instance, the fragmentation process should take into account dependencies among attributes in the original relation. In fact, dependencies could be exploited by observers to reconstruct the association among attributes appearing in different fragments. As an example, the specialty of a patient's doctor may reveal the disease the patient suffers from (e.g., an oncologist takes care of people suffering from cancer). Furthermore, all the proposals in the literature protect only the confidentiality of static datasets. In real-world scenarios, however, outsourced data collections are subject to frequent changes that should be carefully managed to prevent information leakage. As an example, the insertion of a tuple into relation Patients in Figure 53.1a translates into the insertion of a tuple into each of the fragments in Table 53.1. An observer can therefore easily reconstruct the sensitive associations among the attribute values for the new tuple.

53.2.2 Efficient Query Evaluation

In the data outsourcing scenario, the storing server does not have complete visibility of the outsourced data, as they are fragmented and/or encrypted to preserve confidentiality. Therefore, it cannot evaluate users' queries. Also neither the data owner should be involved in the query evaluation process (this would nullify the advantages of data outsourcing), nor the client should download the complete outsourced data collection to locally evaluate queries. It is therefore necessary to define techniques that permit to partially delegate to the external server the query evaluation process, while not opening the door to inferences.

Solutions: In the last few years, several techniques have been proposed to support the server-side evaluation of a wide set of selection conditions and SQL clauses when the outsourced relation is completely encrypted. These solutions complement the encrypted relation with additional metadata, called *indexes*, on which queries are evaluated at the server side. Relation r, defined over schema $R(a_1,\ldots,a_n)$, is then mapped to an encrypted relation r^k over schema R^k (`tid`, `enc`, $I_{i1},\ldots,I_{ij}$), with `tid` a numerical attribute added to the encrypted relation and acting as a primary key for R^k; `enc` the encrypted tuple; $I_{il}, l = 1,\ldots,j$, the index associated with the i_l-th attribute a_{il} in R. For instance, Table 53.2 illustrates the encrypted version of relation Patients in Figure 53.1a, assuming the presence of indexes for `DoB` ($I_{\texttt{Dob}}$), `ZIP` ($I_{\texttt{ZIP}}$), and `Race` ($I_{\texttt{Race}}$). For readability, index values are represented with Greek letters, and we report the tuples in the plaintext and encrypted relations in the same order. Note, however, that the order in which tuples are stored in the encrypted relation is

TABLE 53.2 An Example of Encrypted Relation with Indexes

PATIENTS^k				
id	enc	I_{DoB}	I_{ZIP}	I_{Race}
1	zKZlJxV	α	δ	η
2	AJvaAy1	α	ε	η
3	AwLBAa1	α	ζ	η
4	mHF/hd8	β	δ	θ
5	HTGhoAq	β	ζ	θ
6	u292mdo	γ	ζ	θ
7	ytOJ;8r	γ	δ	θ
8	eWo09uH	γ	ε	ι

independent from the order in which they appear in the plaintext relation. Different indexing techniques support different types of queries. In the following, we illustrate some techniques, partitioning them according to the queries that each of them can manage.

- *Equality conditions* (e.g., [19,39]): The first approach proposed to support equality conditions is represented by *encryption-based indexes* [19]. Given a tuple t, the value of the index for attribute a is computed as $E_k(t[a])$, where E_k is a symmetric encryption function and k the encryption key. As a consequence, any condition of the form $a = v$ is translated as $I_a = E_k(v)$. For instance, consider index $I_{\texttt{Race}}$ in Table 53.2 obtained by adopting this method. Then, condition `Race` = 'Asian' on relation PATIENTS is translated as $I_{\texttt{Race}} = E_k$ (Asian), that is, I_{Race} = 'η' on relation PATIENTS^k. An alternative solution is represented by *bucket-based indexes* [39]. The domain of attribute a is partitioned into nonoverlapping subsets of contiguous values, and each partition is associated with a label. Given a tuple t in the outsourced relation r, the value of the index associated with attribute a is the label of the unique partition containing value $t[a]$. As a consequence, equality condition $a = v$ is translated as $I_a = l$, where l is the label of the partition including v. For instance, index $I_{\texttt{DoB}}$ in Table 53.2 has been obtained by partitioning the domain [1980/01/01, 1980/12/31] of attribute `DoB` in intervals of 4 months, and assigning, in the order, labels α, β, and γ to the three partitions. Condition `DoB` = 1980/04/15 on relation PATIENTS is translated as $I_{\texttt{DoB}}$ = 'β' on PATIENTS^k, since β is the label for the partition [1980/04/01, 1980/07/31]. A third technique efficiently supporting equality conditions is represented by *hash-based indexes* [19]. Given a tuple t in r, the value of the index associated with attribute a is computed as $h(t[a])$, where h is a deterministic hash function that generates collisions. Therefore, condition $a = v$ is translated as $I_a = h(v)$. For instance, consider index $I_{\texttt{ZIP}}$ in Table 53.2 obtained by adopting this method. Then, condition `ZIP` = 22010 on relation PATIENTS is translated as $I_{\texttt{ZIP}} = h(22010)$, that is, $I_{\texttt{ZIP}}$ = 'δ' on relation PATIENTS^k. Both bucket-based and hash-based indexes map different plaintext values to the same index value. Therefore, the result computed by the server may include *spurious tuples* that the client will filter out by executing a query that evaluates the original condition on the tuples received from the server (after their decryption). For instance, only two of the three tuples in the encrypted relation with value 'δ' for attribute $I_{\texttt{ZIP}}$ satisfy condition `ZIP` = 22010.
- *Range conditions* (e.g., [2,19,64]): To overcome the limitations of indexing techniques that support only equality conditions, in [19], the authors present a B+-tree index that allows the evaluation of both equality and range queries at the server side. The B+-tree index is built by the data owner over the original plaintext values of an attribute. It is then represented as a relational table, encrypted, and stored at the server. This relation is iteratively queried by the client for retrieving the tuples satisfying the query condition. For instance, Figure 53.2 illustrates the B+-tree index built for attribute `Name` of relation PATIENTS in Figure 53.1a, the relation representing it, and

FIGURE 53.2 An example of *B*+-tree index (a), its relational representation (b), and the corresponding encrypted relation (c).

the encrypted relation stored at the external server. Condition Name LIKE ‘[E–Z]%’ on relation Patients (retrieving the names following ‘E’ in lexicographic order) is evaluated by executing a set of queries for traversing the *B*+-tree along the path of nodes 1, 3, and 9, and to follow the chain of leaves starting at node 9. For each visited leaf, the client retrieves the tuple associated with it (i.e., tuple t_5 for leaf 9, tuple t_6 for leaf 10, tuple t_7 for leaf 11, and tuple t_8 for leaf 12). To avoid storing additional relations on the server, *order-preserving encryption indexes* have recently been proposed [2,64]. These techniques are based on order-preserving encryption schemas, which take as input a target distribution of index values and apply an order-preserving transformation in a way that the transformed values (i.e., the index values) follow the target distribution.

- *Aggregate operators* (e.g., [33,38]): Privacy homomorphic encryption [61] allows the execution of basic arithmetic operations (i.e., +, −, ×) directly over encrypted data. Their adoption in the definition of indexes allows the server to evaluate aggregate functions and to execute equality and range queries. The main drawback of these approaches is their computational complexity, which makes them not suitable for many real-world applications.

The main challenge that must be addressed in the definition of indexing techniques is balancing precision and privacy: more precise indexes provide more efficient query execution, at the price of a greater exposure to possible privacy violations. As an example, encryption-based indexes permit to completely delegate the evaluation of equality conditions to the server. However, index values have exactly the same frequency distribution as plaintext values, thus opening the door to frequency-based attacks. For instance, it is easy to see that value ι for index $I_{\texttt{Race}}$ represents value *black* for attribute Race, since *black* (ι, respectively) is the only value with one occurrence for attribute Race (index $I_{\texttt{Race}}$, respectively). Analogously, a higher number of indexes on the same relation improve query evaluation efficiency, while causing a higher risk of inference and linking attacks. As shown

in [10], even a limited number of indexes can greatly facilitate the task for an adversary who wants to violate the confidentiality provided by encryption.

The evaluation of queries over outsourced data requires the definition of proper techniques defining how queries on the original table are translated into queries on the encrypted data and indexes over them, or on fragmented data. For instance, consider relation PATIENTS in Figure 53.1a and its fragmentation in Table 53.1. Query "SELECT `Name` FROM PATIENTS WHERE `Disease` = 'flu'" is translated into the following query operating on fragment F_2, where attribute `Disease` is represented in clear from: "SELECT `enc` FROM F_2 WHERE `Disease` = 'flu.'" When the client receives the query result, it decrypts attribute `enc` and applies a projection on patient's names before showing the result to the requesting user. Query plans are designed to minimize the client's overhead in query evaluation. In fact, most query evaluations will require the client's intervention since the server cannot decrypt encrypted attributes. The techniques designed to define efficient query plans depend on the fragmentation approach adopted (e.g., [13,15,31]).

Open issues: Besides the definition of alternative indexing techniques for encrypted data and for efficiently evaluating queries on fragmented data, it still remains to study the possibility of combining fragmentation and indexing approaches. In fact, fragmentation does not permit to delegate the evaluation of conditions involving attributes that do not appear plaintext in a fragment. The association of indexes to fragments could nicely fill this gap, but should be carefully designed to prevent information leakage caused by the plaintext representation in a fragment of an attribute indexed in another.

53.2.3 Access Control Enforcement

In most real-world systems, access to the data is selective; that is, different users enjoy different views over the data. When the data are managed by an external third party, the problem of how to enforce the access control policy defined by the owner becomes crucial. In fact, the data owner cannot enforce the access control policy since this would imply that the data owner has to mediate every access request, thus losing advantages of outsourcing data. Also access control enforcement cannot be delegated to the external server as in traditional systems (e.g., [6]) for privacy reasons. Indeed, the access control policy might be sensitive, and the server might collude with malicious users to gain access to sensitive data. Therefore, it is necessary to define techniques that permit the data themselves to enforce access control policies.

Solutions: The solutions proposed to enforce access control restrictions on outsourced data without the data owner's intervention are based on integrating access control and encryption.

The enforcement of read privileges has been addressed first and has been efficiently solved by mapping selective visibility restrictions in the encryption of the data [23]. The authorization policy is translated into an equivalent *encryption policy*, regulating which data are encrypted with which key and which keys are released to which users. This translation process is performed considering the following two desiderata: (1) at most one key is released to each user, and (2) each tuple is encrypted at most once. To this purpose, the approach in [23] adopts a key derivation method, which permits to compute an encryption key k_i starting from the knowledge of another key k_j and a piece of publicly available information [4]. Key derivation methods are based on the definition of a key derivation hierarchy that specifies which keys can be derived from other keys in the system. A key derivation hierarchy that correctly enforces the access control policy must permit each user to derive from her key all and only the keys used to encrypt the tuples she can access. To this aim, the hierarchy has a node (which represents a key) for each user in the system and a node for each access control list (acl), that is, for each set of users who can access a tuple. The edges in the hierarchy (which correspond to key derivation operations) guarantee the existence of a path connecting each node representing a user to each node representing a set to which the user belongs [23]. Each user knows the key of the node representing herself in the hierarchy and each resource is encrypted with the key representing its access control list. For instance, consider a system with four users $\{L, M, N, O\}$

Tuple	Read acl
t_1	*L*
t_2	*LM*
t_3	*LM*

t_7	k_{LMO}
t_8	k_O

(d)

FIGURE 53.3 An example of access control policy (a), the corresponding key derivation graph (b), keys assigned to users (c), and keys used to encrypt resources (d).

and the tuples composing relation Patients in Figure 53.1a. Figure 53.3b reports the key derivation graph enforcing the access control policy in Figure 53.3a, and Figures 53.3c and d summarize the keys communicated to the users and the keys used to encrypt the tuples. For simplicity and readability, in the key derivation graph, nodes are labeled with the set of users they represent. It is easy to see that each user knows or can derive all and only the keys of the nodes including herself. As a consequence, she can decrypt all and only the tuples in relation Patients that she is authorized to access (i.e., such that the user belongs to the acl of the tuple).

The solution in [25] complements the technique in [23] by associating a write token with each tuple. The write token is encrypted with a key that only users who can modify the tuple and the external server can derive. The server accepts a write operation only if the requesting user proves to be able to correctly decrypt the write token associated with the modified tuple. For instance, Figure 53.4a illustrates the access control policy in Figure 53.3a for relation Patients, extended with write privileges on the tuples. Figure 53.4b illustrates the key derivation graph, which extends the graph in Figure 53.3b introducing the external server S. Figures 53.4c and d summarize the keys communicated to the users and the keys used to encrypt the tuples and the corresponding write tokens.

The enforcement of access control restrictions through encryption raises many other issues that have been recently addressed, as summarized in the following.

- Since the key used to encrypt each tuple depends on the set of users who can access it, updates to the access control policy require data re-encryption, which represents an expensive operation for the data owner. For instance, consider the example in Figure 53.3 and assume that user *O* is revoked access to tuple t_5. To enforce such a revocation, the data owner should download tuple t_5, decrypt it using key k_{LMNO}, re-encrypt the tuple with key k_{LMN}, and send it back to the server. To prevent re-encryption, while enforcing updates to the access control policy, the proposal

Tuple	Read acl	Write acl

(d)

FIGURE 53.4 An example of read-and-write access control policy (a), the corresponding key derivation graph (b), keys assigned to users (c), and keys used to encrypt resources (d).

in [23] adopts two layers of encryption: one managed by the data owner and enforcing the initial policy (BEL); and the other managed by the external server and enforcing policy updates (SEL). A user can then access a tuple only if she knows (or can derive) the key used for encrypting the resources at both levels.

- The adoption of key derivation for access control enforcement may reveal to the server the authorization policy. Whenever the policy is considered sensitive, the structure of the key derivation hierarchy should not be revealed to the external server, as proposed in [21].
- Many real-world scenarios are characterized by parties acting both as data producers (i.e., data owners) and as data consumers (i.e., final users). The enforcement of access control should then take into consideration the fact that there are multiple data owners, each regulating access to her data [22].
- The combined use of selective encryption (for access control enforcement) and indexing techniques (for efficient query evaluation) may open the door to inference on attribute values of tuples that users are not authorized to read [24]. In fact, users have also visibility on indexes of tuples they are not allowed to access. Since index values depend on the attribute value they represent, such a visibility could permit users to infer attribute values for tuples they cannot access. For instance, consider plaintext relation Patients in Figure 53.1a, its encrypted version in Table 53.2, and the access control policy in Figure 53.3a. User M, who is authorized to read tuple t_2, can easily infer that value η for index $I_{\texttt{Race}}$ represents plaintext value 'Asian'. As a consequence, M can conclude that t_1 [`Race`] = 'Asian', thus breaching the confidentiality of tuple t_1 that she is not authorized to access. To limit this risk, the indexing function should be designed to take access control restrictions into consideration [24].

An alternative solution to the combined use of selective encryption and key derivation for access control enforcement has been introduced in [71]. This approach aims at providing systems scalability by adopting *attribute-based encryption*. In this scenario, the traditional access control policy is substituted by the definition of a set of attributes associated with users and tuples regulating which user can access which tuple. More precisely, each tuple is associated with a set of attributes that describe the context in which the tuple should be accessed, and each user is associated with a logical expression over the attributes that represents the properties of the tuples she is authorized to access. To enforce the access control policy, attribute-based encryption techniques define a different public key component for each attribute in the system. Each tuple is then encrypted using a key that reflects all the public key components of the attributes associated with it, while each user knows the secret key that permits to decrypt all the tuples she is authorized to access.

Open issues: Most of the problems studied for the enforcement of read privileges need to be analyzed also for the solutions enforcing write privileges. For instance, it is necessary to define an efficient approach for managing policy updates without the intervention of the data owner and a technique for protecting the confidentiality of the policy when read-and-write operations are restricted to arbitrary subsets of users.

53.3 Security Issues in the Data Publishing Scenario

In the data publishing scenario, information about entities, called *respondents*, are publicly or semipublicly released. While in the past, released information was mostly in tabular and statistical form (*macrodata*), many situations require today the release of specific data (*microdata*). Microdata provide the convenience of allowing the final recipient to perform on them analysis as needed, at the price of a higher risk of exposure of respondents' private information. In this section, we describe how public data release may cause the unintended disclosure of respondents' identities and/or sensitive attributes, and the solutions proposed to counteract this risk.

53.3.1 Preserving Respondents' Privacy

To protect respondents' identities, data owners remove or encrypt explicit identifiers (e.g., SSN, name, phone numbers) before publishing their datasets. However, data *de-identification* provides no guarantee of anonymity since released information often contains other data (e.g., race, birth date, sex, and ZIP code) that can be linked to publicly available information to reidentify (or restrict the uncertainty about the identity of) data respondents, thus leaking information that was not intended for disclosure. The large amount of information easily accessible today, together with the increased computational power available to data recipients, makes such linking attacks easier [35]. Furthermore, the disclosure of an individual's identity (*identity disclosure*) often implies also the leakage of her sensitive information (*attribute disclosure*). For instance, in 2006, Netflix, an online DVD delivery service, started a competition whose goal was the improvement of its movie recommendation system based on users' previous ratings. To this purpose, Netflix released 100 million records about movie ratings of 500,000 of its subscribers. The released records were anonymized removing the personal identifying information of the subscribers, which was substituted with an anonymous customer id. However, by linking the movie recommendations available on the Internet Movie Database with the anonymized Netflix dataset, it was possible to reidentify individuals, thus revealing potentially sensitive information (e.g., apparent political preferences) [55].

Protecting respondents' identities and sensitive attributes in the today's global interconnected society is a complex task that requires the design of effective techniques that permit data owners to provide privacy guarantees, even without knowing the external sources of information that a possible observer could exploit to reidentify data respondents. Note that the public release of a dataset should also provide utility for data recipients (i.e., the released dataset should include as much information as possible to permit final recipients to obtain representative results from their analysis). Clearly, data utility and privacy are two conflicting requirements that need to be balanced in data release.

Solutions: The solutions proposed to protect respondents' privacy, while providing data recipients with useful data, can be classified in the following two categories:

1. *Approaches based on k-anonymity* (e.g., [46,49,62]) guarantee that the dataset publicly released satisfies properties that provide protection against identity and attribute disclosure (e.g., every combination of values of quasi-identifiers can be indistinctly matched to at least k respondents).
2. *Approaches based on differential privacy* (e.g., [30,41]) guarantee that the released dataset is protected against certain kinds of inference defined before data release (e.g., an observer cannot infer with non-negligible probability whether a subject is represented in the released dataset).

The first approach proposed in the literature to protect respondents' privacy in microdata release is represented by *k-anonymity* [62]. k-Anonymity captures the well-known requirement, traditionally applied by statistical agencies, stating that any released data should be indistinguishably related to no less than a certain number of respondents. Since linking attacks are assumed to exploit only released attributes that are also externally available (called *quasi-identifiers*), in [62], this general requirement has been translated into the following k-anonymity requirement: *Each release of data must be such that every combination of values of quasi-identifiers can be indistinctly matched to at least k respondents*. A microdata table then satisfies the k-anonymity requirement if each tuple in the table cannot be related to less than k respondents in the population and vice versa (i.e., each respondent in the population cannot be related to less than k tuples in the released table). The k-anonymity requirement can be checked only if the data owner knows any possible external source of information that may be exploited by a malicious recipient for respondents' reidentification. This assumption is, however, limiting and highly impractical in most scenarios. k-Anonymity then takes a safe approach by requiring that each combination of values of the quasi-identifier attributes appears with at least k occurrences in the released table, which is a sufficient (although not necessary) condition to satisfy the k-anonymity requirement. Traditional approaches for guaranteeing k-anonymity transform the values

TABLE 53.3 An Example of 2-Anonymous Table

Patients						
SSN	Name	DoB	ZIP	Race	Disease	Doctor
		1980/02	2201*	Asian	Flu	I. Smith
		1980/02	2201*	Asian	Gastritis	J. Taylor
		1980/06	2204*	White	Hypertension	L. Green
		1980/06	2204*	White	Asthma	K. Doe
		1980/10	2201*	White	HIV	L. Green
		1980/10	2201*	White	HIV	L. Green

of the attributes composing the quasi-identifier, while leaving sensitive attribute values unchanged. To guarantee truthfulness of released data, k-anonymity relies on *generalization* and *suppression* microdata protection techniques [17]. Generalization consists in substituting the original values with more general values (e.g., the date of birth can be generalized by removing the day, or the day and the month, of birth). Suppression consists in removing data from the microdata table. The combined use of these techniques guarantees the release of a less precise and less complete, but truthful, data while providing protection of respondents' identities. As an example, Table 53.3 has been obtained from the table in Figure 53.1a by (i) removing explicit identifiers (i.e., `SSN` and `Name`); (ii) generalizing attribute `DoB` removing the day of birth; (iii) generalizing attribute `ZIP` removing the last digit; and (iv) suppressing the third and eight tuples in the original table. The resulting table is 2-anonymous since each combination of values for attributes `DoB`, `Race`, and `ZIP` appears (at least) twice in the relation. To limit the information loss caused by generalization and suppression (i.e., to improve utility of released data), many k-anonymity algorithms have been proposed (e.g., [5,16,42,43,62]). All these approaches are aimed at minimizing the loss of information caused by generalization and suppression, while providing the privacy guarantees required by respondents. Although k-anonymity represents an effective solution for protecting respondents' identities, it has not been designed to protect the released microdata table against attribute disclosure. Given a k-anonymous table, it may then be possible to infer (or reduce the uncertainty about) the value of the sensitive attribute associated with a specific respondent. This happens, for example, when all the tuples with the same value for the quasi-identifier are associated with the same value for the sensitive attribute. For instance, consider Table 53.3, which is 2-anonymous, and assume that *Susan* knows that her friend *Frank* is a male, born in October 1980, and living in 22015 area. *Susan* can easily infer that *Frank*'s tuple is either the fifth or the sixth tuple in the published table. As a consequence, *Susan* can infer that her friend suffers from HIV. ℓ-Diversity [49] and t-closeness [46] have been proposed to protect released microdata tables against attribute disclosure.

Approaches based on the definition of differential privacy [30] have been recently proposed to guarantee that the released microdata table protects respondents against inference that exploits both published data and external adversarial knowledge. One of the first definitions of privacy in the data publishing scenario states that *Anything that can be learned about a respondent from the statistical database should be learnable without access to the database* [18]. Although this definition has been thought for statistical databases, it is also well suited for the microdata publishing scenario. However, the main problem of this definition of privacy is that only an empty dataset can guarantee absolute disclosure prevention [30]. Differential privacy can be considered as the first attempt of achieving privacy as defined in [18]. It is based on the observation that the release of a dataset may violate the privacy of any individual, independently of whether she is represented in the dataset. For instance, suppose that the released dataset permits to compute the average annual benefits of people living in 22010 area for each ethnic group and suppose that this information is not publicly available. Assume also that *Alice* knows that *Bob*'s annual benefits is 1,000$ more than the average

annual benefits of Asian people living in 22010 area. Although this piece of information alone does not permit *Alice* to gain any information about *Bob*'s annual benefits, when it is combined with the released dataset, it allows Alice to infer *Bob*'s annual benefits. Differential privacy aims at preventing an observer from inferring whether a subject is represented or not in the released dataset. A data release is then considered safe if the inclusion in the dataset of tuple t_p, related to respondent p, does not change the probability that a malicious recipient can correctly identify the sensitive attribute value associated with p. Intuitively, differential privacy holds if the removal (insertion, respectively) of one tuple t_p from (into, respectively) the table does not substantially affect the result of the evaluation of a function K on the released table. Most of the techniques proposed to satisfy differential privacy are based on *noise addition*, which does not preserve the truthfulness of released data (e.g., [40,44,51,67]) and may therefore not be suited to different data publishing scenarios. Differential privacy provides protection against inferences on the presence/absence in the published dataset of the record representing a respondent. However, this is not the only cause of privacy breaches. To provide a wider privacy guarantee, a recent line of work has put forward a definition of privacy that permits to protect released data against any kind of inference, provided it is defined (and properly modeled) by the data owner before data release [41].

Open issues: Although many efforts have been made to overcome the assumptions on which the definitions of k-anonymity and differential privacy are based, there are still open issues that deserve further investigation. This is also testified by the fact that there is not a unique definition of respondents' privacy and each definition has some drawbacks that need to be addressed (e.g., external adversarial knowledge is not adequately modeled and addressed by privacy protection techniques). Also all the proposed solutions for protecting respondents' privacy still need to be enhanced, to possibly find a good trade-off between privacy of respondents and utility of released data for final recipients.

53.4 Security Issues in Emerging Scenarios

In this section, we focus on the security and privacy problems that are common to both the data outsourcing scenario and the data publishing scenario. In particular, we consider the (i) confidentiality of users' queries; (ii) integrity of outsourced/published data; and (iii) completeness and correctness of query results.

53.4.1 Private Access

An important issue that arises when data are stored at an external server is preserving the confidentiality of users' queries, independently of whether data are kept confidential or are publicly released. As an example, assume that a user accesses an external medical database looking for the symptoms of a given disease. The server executing the query (as well as any observer) can easily infer that the user (or a person close to her) suffers from the disease in the query condition. Furthermore, queries could be exploited by the server (or by an external observer) to possibly infer sensitive information in the outsourced data collection, thus reducing the effectiveness of the techniques possibly adopted by the data owner to protect data confidentiality. Besides protecting the confidentiality of each query singularly taken, it is also important to protect *patterns* of accesses to the data (i.e., the fact that two or more queries aimed at the same target tuple). Indeed, the frequency of accesses to tuples could be exploited to breach both data and query confidentiality.

Solutions: The solutions proposed to protect the confidentiality of the queries issued by users can be classified depending whether they operate on plaintext data (data publishing) or on encrypted data (data outsourcing).

The line of work first developed to protect query confidentiality is represented by classical studies on *Private Information Retrieval* (PIR) [12], which operates on plaintext datasets stored at an external server. In this model, the database is represented as an N-bit string and a user is interested in retrieving the ith bit of the string without allowing the server to know/infer which is the bit target of her query.

PIR proposals can be classified as follows: *information-theoretic* PIR, which protects query confidentiality against attackers with unlimited computing power; and *computational* PIR, which protects query confidentiality against adversaries with polynomial-time computing power. Unfortunately, information-theoretic PIR protocols have computation and communication costs linear in the size of the dataset (i.e., $\Omega(N)$) as there is no solution to the problem that is better than downloading the whole database [12]. To limit these costs, it is however possible to replicate the dataset on different servers. Intuitively, PIR approaches exploiting data replication require the user to pose a randomized query to each server storing a copy of the dataset, in such a way that neither the servers nor an outside observer can determine which is the bit to which the user is interested. The user will then reconstruct the target bit by properly combining the query results computed by the different servers [3,12]. The main problem of these proposals is that they rely on the unrealistic assumption that the external servers do not communicate with each other. Computational PIR protocols exploit cryptographic properties to reduce both the communication cost and the number of copies of the data with respect to information-theoretic techniques [8,11]. Users then adopt specific functions to encrypt their requests before submitting them to the server. These functions enjoy particular properties that allow the server to compute, without decrypting the request, an encrypted query result that only the requesting user can decrypt. Although more efficient than information-theoretic solutions, also computational PIR schemes suffer from heavy computation costs (i.e., $O(N)$ or $O(\sqrt{N})$) both for the client and for the server, which limit their applicability in real-life scenarios [32]. Recently, traditional PIR protocols have been integrated with relational databases, to the aim of protecting sensitive constant values in SQL query conditions, while providing the client with efficient query evaluation [56]. The original query formulated by the client is properly sanitized before execution, to prevent the server from inferring sensitive data. To extract the tuples of interest from the result of the sanitized query executed by the server, the client then resorts to traditional PIR protocols, operating on the sanitized query result instead of on the whole dataset (thus highly reducing computational costs).

One of the solutions operating on encrypted data, aimed at providing both data and query confidentiality, is based on the definition of a *shuffle index* on the data collection [26,27]. A shuffle index is defined, at the abstract level, as an *unchained B+-tree* (i.e., there are no links connecting the leaves), built on one of the attributes in the outsourced relation and with actual data stored in the leaves of the tree. Figure 53.5a illustrates a graphical representation of the abstract data structure built on attribute `Name` of relation PATIENTS in Figure 53.1a. At the logical level, the nodes of the tree are allocated to logical addresses that work as logical *identifiers*, which may not follow the same order of the values in the abstract nodes they represent. Figure 53.5b illustrates a possible representation at the logical level of the abstract data structure in Figure 53.5a. In the figure, nodes appear ordered (left to right) according to their identifiers, which are reported on the top of each node. Pointers between nodes of the abstract data structure correspond, at the logical level, to node identifiers, which can then be easily translated at the physical level into physical addresses at the external server. For simplicity and easy reference, in our example, the first digit of the node identifier denotes the level of the node in the tree. Before sending to the server the shuffle index for storing it, the content of each node is encrypted, producing an encrypted block. Since each block is encrypted, the server does not have any information on the content of the node stored in the block or on the parent–child relationship between nodes stored in blocks. Retrieval of the leaf block containing the tuple corresponding to an index value requires an iterative process. Starting from the root of the tree and ending at a leaf, the read block is decrypted retrieving the address of the child block to be read at the next step. To protect access and pattern confidentiality, searches over the *B*+-tree are extended with the following three protection techniques [26].

- *Cover searches*: fake searches executed together with the target search. The values used as cover searches are chosen to be indistinguishable from actual target values and operate on disjoint paths of the tree. The search process retrieves, for each level in the tree, the same number of blocks (one for the target and the other for the cover searches). Cover searches introduce uncertainty over the leaf block storing the target tuple and do not allow the server to establish the parent–child relationship between blocks retrieved at contiguous levels.

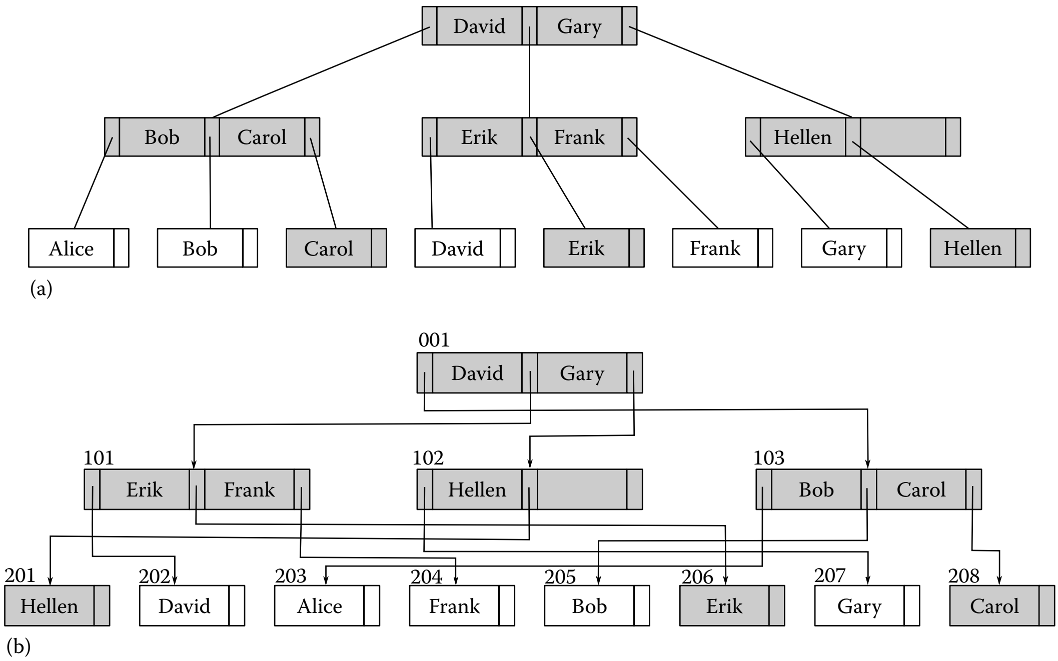

FIGURE 53.5 An example of abstract (a) and corresponding logical shuffle index (b).

- *Cache*: set of blocks/nodes along the path to the target value recently accessed, which are stored at the client side. Cache makes searches repeated within a short time interval not recognizable as being the same search: if the nodes in the target path are already in cache, an additional cover search is executed.
- *Shuffling*: operation performed for changing the block where accessed nodes are stored, thus breaking the correspondence between nodes (contents) and blocks (addresses). Basically, the contents of blocks retrieved at each level and of the blocks at the same level stored in the local cache are mixed. Nodes are then re-encrypted, and the resulting blocks rewritten accordingly on the server.

As an example, consider a search for the name *Carol* over the abstract index in Figure 53.5a that adopts *Hellen* as cover and assume that the local cache contains the path to *Erik* (i.e., (001,101,204)). The nodes involved in the search operation are denoted in gray in the figure. Figure 53.6 illustrates the abstract and logical representation of the shuffle index in Figure 53.5 after the execution of the search operation, which shuffles nodes 101, 102, and 103, and nodes 201, 206, and 208.

Besides the shuffle index technique, other proposals have also been introduced to address data and query confidentiality in data outsourcing scenarios. These approaches are based on the pyramid-shaped database layout of Oblivious RAM [34] and propose an enhanced reordering technique between adjacent levels of the structure [20,29,47,66]. The privacy provided by these approaches is guaranteed however by the presence of a trusted coprocessor at the external server.

Open issues: Among the open issues that still need to be analyzed, there are the needs of providing efficient accesses based on the value of different attributes in the outsourced/published relation (*multiple indexes*) and of supporting possible updates to the data collection.

53.4.2 Data Integrity

Traditionally, the server is assumed to be trusted to correctly store and maintain the data of the owners. There are, however, scenarios where such a trust assumption does not hold. As a consequence, the server

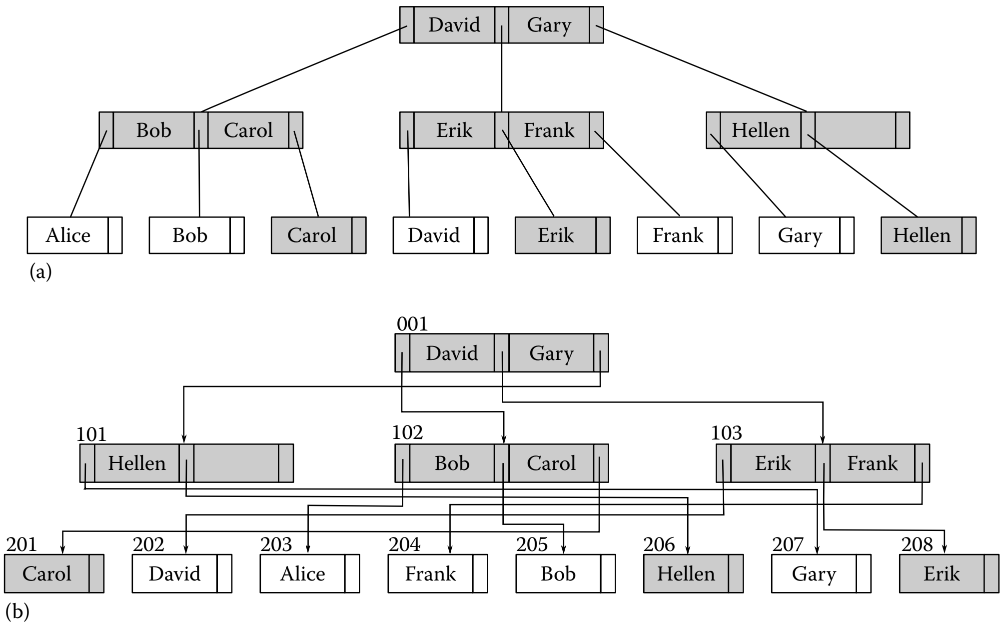

FIGURE 53.6 Abstract (a) and corresponding logical shuffle index (b) in Figure 53.5 after the execution of a search operation.

itself or a user may modify the data collection without being authorized. Since the server directly stores and manages the dataset, it is not possible to physically prevent unauthorized data modifications; there are however techniques that permit the data owner (and any authorized user) to discover non-authorized modifications.

Solutions: Data integrity can be provided at different granularity levels: table, attribute, tuple, or cell level. The integrity verification at the table and attribute level is expensive since it can be performed by the client only downloading the whole table/column. Data integrity at the cell level suffers from a high verification overhead. For these reasons, the majority of the current proposals provide data integrity at the tuple level.

Integrity verification approaches traditionally rely on *digital signatures* (e.g., [37]), that is, the data owner first signs, with her private key, each tuple in the outsourced/published relation, and the signature is concatenated to the tuple. When a client receives a set of tuples from the external server, she can check the signature associated with each tuple to detect possible unauthorized changes. The main drawback of traditional integrity verification techniques relying on digital signature is that the verification cost at the client side grows linearly with the number of tuples in the query result.

To reduce the verification costs of large query results, in [53], the authors propose the adoption of a schema that permits to combine a set of digital signatures. In this way, the client can verify the integrity of the query result by checking one aggregated signature only: the one obtained combining the signatures of the tuples in the query result. In [53], the authors propose three different signature schemes: *condensed RSA*, based on a variation of the RSA encryption schema that allows the aggregation of signatures generated by the same signer; *BGLS* [7], based on bilinear mappings and supporting the aggregation of signatures generated by different signers; batch *DSA signature aggregation*, based on the multiplicative homomorphic property of DSA signature schema. Both condensed RSA and BGLS approaches are *mutable*, meaning that any user who knows multiple aggregated signatures can compose them, obtaining a valid aggregated signature. Although this feature can be of interest in the process of generating aggregated signatures, it also represents a weakness for the integrity of the data. In [52],

the authors propose an extension of condensed RSA and BGLS techniques that makes them immutable. Such an extension is based on zero knowledge protocols and basically consists in revealing to the client a proof of the knowledge of the aggregated signature associated with the query result, instead of revealing the signature itself.

Open issues: Current approaches for providing integrity guarantees to externally stored data typically adopt signature techniques. These solutions are, however, computationally expensive both for the data owner and for clients. It could be useful to define alternative approaches based on less expensive techniques that permit authorized users to efficiently check data integrity.

53.4.3 Completeness and Correctness of Query Results

Besides techniques that permit to discover unauthorized changes (data integrity in storage), it is also necessary to provide clients with methods for verifying the correctness and completeness of query results. Indeed, the external server may be lazy in computing the query result and omit tuples from the computation, or include fake tuples in the query result. The verification of query results is hard to enforce, especially in the emerging large-scale platforms used, for example, in cloud computing.

Solutions: The approaches proposed in the literature can be classified as follows.

- *Authenticated data structures* approaches (e.g., [28,45,50,54,57,58,70]) are based on the definition of appropriate data structures (e.g., signature chaining, Merkle hash trees, or skip lists) and provide guarantee of completeness of the result of queries operating on the attribute (set thereof) on which the data structure has been defined. These approaches also guarantee integrity of stored data since unauthorized changes to the data can be detected by the verification process of query results.
- *Probabilistic* approaches (e.g., [48,65,68]) are based on the insertion of sentinels in the outsourced data, which must also belong to the query result. These solutions provide a probabilistic guarantee of completeness of query results.

Most of the authenticated data structure approaches adopt *Merkle hash trees* [50]. A Merkle hash tree is a binary tree, where each leaf contains the hash of one tuple of the outsourced relation, and each internal node contains the result of the application of the same hash function on the concatenation of the children of the node itself. The root of the Merkle hash tree is signed by the data owner and communicated to authorized users. The tuples in the leaves of the tree are ordered according to the value of a given attribute *a*. Figure 53.7 illustrates an example of a Merkle hash tree built over relation PATIENTS in Figure 53.1a

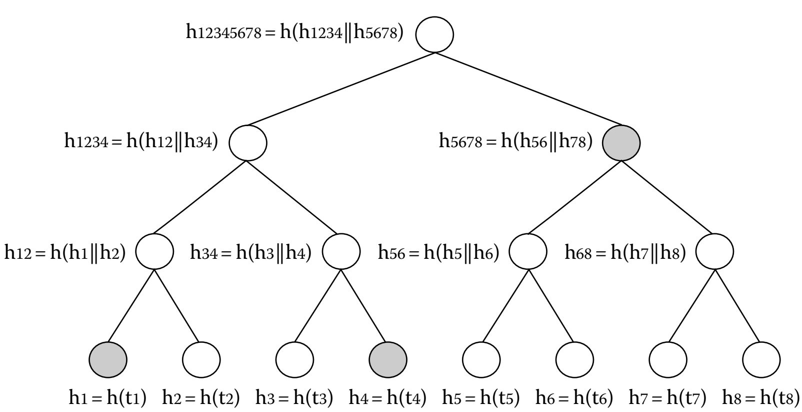

FIGURE 53.7 An example of Merkle hash tree.

for attribute SSN. Whenever the external server evaluates a query with a condition defined on a, it returns to the requesting client the result of the query along with a *verification object* (VO). The VO includes all the information that the client needs to know to verify the completeness of the query result (i.e., to recompute the value of the root node) [28]. If the value of the root node computed by the user is the same as the one received from the owner, the query result is correct and complete. For instance, consider the Merkle hash tree in Figure 53.7: the VO for a query that returns the patients whose SSN starts with either 2 or 3 (i.e., tuples t_2 and t_3) is represented by the gray nodes in the figure. Solutions based on authenticated data structures have the advantage of providing 100% guarantee of completeness of query results. The main problem is that these data structures can be used only for queries with conditions on the specific attribute on which they are built. This implies that the completeness of queries operating on different attributes can be checked only at the price of defining an additional authenticated data structure for each attribute.

Probabilistic approaches are based on the insertion of *fake tuples* or on the *replication* of a subset of the tuples in the outsourced/published relation. The approach based on the insertion of fake tuples [68] checks the completeness of query results by verifying whether all the fake tuples that satisfy the conditions specified in the query belong to the result computed by the server. If at least a fake tuple is missing, the query result is not complete. Clearly, fake tuples must be indistinguishable at the server's eyes from real tuples. As proved in [68], even a limited number of fake tuples ensure a high probabilistic guarantee of completeness. The solution based on the replication of a subset of the outsourced tuples [65] provides guarantee of completeness of the query result by controlling whether tuples in the query result that satisfy the condition for duplication appear twice in the query result. If a tuple that has been duplicated appears only once in the query result, the server omitted at least a tuple. Clearly, the server should not be able to determine pairs of encrypted tuples that represent the same plaintext tuple. The guarantee of completeness provided by probabilistic approaches increases with the number of additional (fake or duplicated) tuples inserted in the dataset.

Recent proposals address the problem of guaranteeing also the *freshness* of query results, meaning that queries are evaluated on the last version of the outsourced relation [45]. To integrate freshness control with solutions based on authenticated data structures, a time stamp is included in the data structure and is periodically updated [69]. If the client knows how frequently the time stamp is updated, it can check whether the VO (and therefore the query result) returned by the server is up-to-date. The solution proposed for probabilistic approaches [68] periodically changes, in a deterministic way, the function that computes fake tuples in the dataset. If the client knows which are the current fake tuples in the outsourced data, it can verify whether the query result includes all and only those valid additional tuples that should be present when the query has been executed.

Open issues: Although the problem of providing guarantees of completeness and freshness of query results is becoming of great interest, there are still many aspects that need to be further investigated. Current solutions consider simple SELECT-FROM-WHERE SQL queries operating on one relation only. However, in many real-world scenarios, it is necessary to assess the correctness and completeness of the result of more complex queries (e.g., queries including GROUP BY and HAVING clauses). Probabilistic approaches provide a good trade-off between completeness guarantee and efficiency in query evaluation. It would be interesting to develop efficient approaches that provide absolute certainty of completeness of query results, while limiting the computational overhead.

53.5 Summary

In this chapter, we illustrated the main security and privacy issues arising in the emerging data outsourcing and data publishing scenarios, where a sensitive data collection is stored and managed by an external third party. For each problem analyzed, the chapter provided an overview of the most important solutions proposed in the literature and described open issues that still need further investigation.

Glossary

Access control list (acl): Set of users who are authorized to access a given resource.
Access control policy: Set of (high-level) rules according to which access control must be regulated.
Confidentiality constraint: Subset of attributes in a relation schema R that should not be jointly visible to unauthorized users.
Data disclosure: Unintended release of (possibly sensitive) information that should not be revealed.
Digital signature: Technique used to prove that a piece of information was created by a known user and that it has not been altered.
Encryption: Process that transforms a piece of information (called plaintext) through an encryption algorithm to make it unintelligible.
Fragmentation: Let R be a relation schema, a fragmentation of R is a set of fragments $\{F_1,\ldots,F_m\}$, where $F_i \subseteq R$, for $i = 1,\ldots,m$.
Index: Piece of additional information stored at the external server together with relation R that can be used to efficiently evaluate queries operating on the attribute on which the index has been defined.
Respondent: Person (or entity) to whom the data undergoing public or semipublic release refer.
Shuffle: Process that randomly changes the assignment of node contents to physical identifiers (i.e., to the block of memory where each node is physically stored).
Verification Object (VO): Piece of information sent to the client by the server executing a query, which can be used by the client to verify whether the query result is correct and complete.

54.1 Introduction

Modern organizations' critical dependencies on information assets have resulted in information security being included among the most important academic research issues within the field of information systems (IS) (Dhillon and Backhouse, 2000; Kankanhalli et al., 2003). The massive amounts of information assets being created every day require management and protection. Technical, administrative, and behavioral controls must be implemented to protect information as it is created, captured, stored, and transmitted. Information at each of these four states of information is vulnerable to security threats. Technical controls, such as firewalls, port scanning, automated backups, intrusion detection systems (IDS), and anti-malware software have introduced significant safeguards against external human perpetrators of security threats, but various human behaviors, especially those of organizational insiders, continue to pose the greatest risk to the security of IS and continue to be cited as the greatest challenge for security practitioners (Davis, 2012; Willison and Warkentin, 2013).

The four goals of the management and protection of information assets are to ensure their confidentiality, integrity, availability, and accountability throughout the organization (Siponen et al., 2006; Stanton et al., 2005; Warkentin and Johnston, 2006, 2008). An information asset's confidentiality is maintained by controlling the methods of disclosure within and beyond the organization. The availability goal is maintained by ensuring that only those individuals authorized to access an information asset are afforded such access only when and where it is required. The maintenance of the integrity of an information asset is achieved through use of controls that restrict asset alterations or deletions. Last, the goal of accountability, more formally known as nonrepudiation, is the assurance that an electronic "paper trail" exists and precludes the denial of transaction occurrences or of the actions of any individual.

Achieving information security within an organization requires development of policies and procedures, followed by their successful implementation (Warkentin and Johnston, 2006, 2008). The information security policies (ISPs) specific to the needs of an organization are developed using the information security goals as a framework. Both formal and informal policies should be aligned with the overall organizational policies and strategies. Procedures and performance standards necessary to support the ISP must be developed and will include specification of the mechanisms and methods for implementation. Finally, the ISPs are put into practice through implementation of the procedures. Employees are informed of the ISP and achieve an appropriate level of understanding of the ISP through information security education, training, and awareness (SETA) campaigns, discussed later.

The various sources and types of threats to information security may be categorized, as shown in Figure 54.1, into internal and external threats and further subdivided into human and non-human threats (Loch et al., 1992; Willison and Warkentin, 2013). Information security and therefore information security research typically focuses on either a technical or behavioral viewpoint (Bulgurcu et al., 2010; Tsohou et al., 2008). The non-human threats that exist include potential events that may occur internally such as equipment failure or events due to external forces such as natural disasters. Human threats in the form of computer hackers or corporate spies are commonly seen in news media headlines (Willison and Siponen, 2009) and as favorites of cinematic thrillers, likely making these external threats the most well known. These external human threats can be subdivided into three categories of perpetrators, any of which may cause harm to the organization, but each fueled by a different intent.

The first category of perpetrators within the external human threat is made of individuals believed to be fueled by curiosity, boredom, and the need for notoriety. These individuals are known as script kiddies, a derogatory term for those who seek out system vulnerabilities to exploit by using software tools, or scripts, developed by others and whose antics are typically considered unsophisticated or childish (Vamosi, 2002; Wlasuk, 2012). Although there is no specific age restriction to be considered a script kiddie, they are typically young but are still quite capable of causing great harm. They have been known to have gained unauthorized access to networks and computer systems, built botnets, and committed web tagging, an electronic form of graffiti.

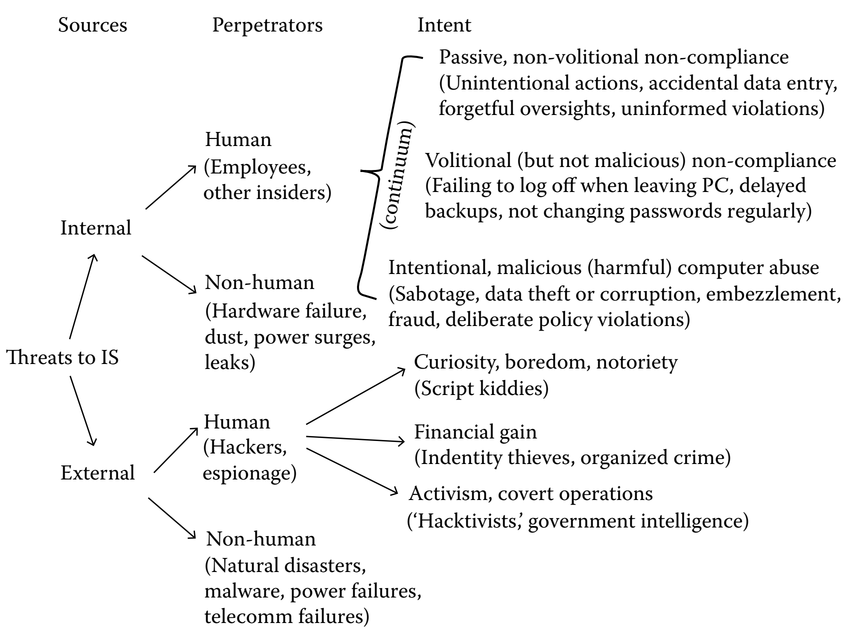

FIGURE 54.1 IS security threat vector taxonomy.

The second category of external human threat perpetrators is made of individuals fueled by the promise of financial gain. These perpetrators have become quite sophisticated and use social engineering methods such as phishing and other forms of deception and psychological techniques to commit fraudulent acts such as theft of intellectual property or of identity theft (Wright and Marett, 2010). These cybercrimes may be committed by individual humans or by members of organized crime syndicates ("Who commits the crime," n.d.). By virtue of the capabilities of the World Wide Web and the Internet, the perpetrators of these crimes can be anywhere in the world, adding to the complexity of their identification and difficulty in punishing them if they are caught.

The last category of perpetrators within the external human threat is made of individuals whose intent is that of activism or covert operations performed by governments. The most well-known perpetrators within this category is the "hactivist" group, Anonymous, who became known to the world in early 2008 when they staged a protest against the Church of Scientology after YouTube was ordered by the church to remove an internal video they claimed was copyrighted (Schwartz, 2012). Since that date, members of Anonymous have been involved in numerous protests and attempts to expose wrongs in the world and have evolved into a culture (Norton, 2011).

Though maintenance of organizational security relies upon employee compliance with ISP, the threats from non-human sources and from humans external to the organization are primarily addressed through maintenance programs and business continuity plans that leverage technological controls such as firewalls and IDS (Cavusoglu et al., 2009), biometrics (Ballard et al., 2007), and encrypted logins (Boncella, 2002). Hardware failures (a prime non-human threat to security) are addressed through both technical and behavioral controls (Malimage and Warkentin, 2010). A great deal of time, effort, and financial resources are spent on protective efforts against these threats, yet research shows that the internal human threat may cause the most harm and be the most difficult to guard against (Doherty and Fulford, 2005; Straub and Welke, 1998; Warkentin and Johnston, 2006; Warkentin and Willison, 2009).

The internal human perpetrators category in Figure 54.1 includes those threats to information security that come from a group of individuals who already have access to the information assets of the organization and are therefore known as the "insider threat." Research in information security (InfoSec) addresses antecedents of and issues related to individual compliance and noncompliance with and criminal violation of IS security policies and procedures. The InfoSec performed to date is the focus of this chapter. We begin with a definition of the term insider threat and a brief discussion of the employee intent continuum shown in Figure 54.1. A review of the theories, methods, and measures used by researchers in this area of study today follows, and the chapter concludes with recently identified major information security research issues and need for future study.

54.2 Information Security Research: The Insider Threat

Who is the insider? Organizational boundaries are dynamic, fluid, and often poorly defined. In the age of the virtual organization and inter-organizational global collaborative teams, many individuals may have access to trusted information resources. In the context of our investigation, there are two essential aspects of an insider: (1) insider access and (2) deep familiarity with organizational processes.

First, the insider must be an individual who has access to information resources not typically provided to the "outsider" (all others in the general public). These resources include systems and their data/information. While this category of individual is typically instantiated as an employee, it should be recognized that he or she may also be a contractor, a virtual partner (supply chain partner or strategic alliance partner with access to resources), or even a constituent who is a customer or other client (e.g., student, medical patient, etc.), provided they have some level of insider privileges. Essentially, the insider is an individual who can easily operate "behind the firewall" who has proper authentication

via password or other methods.* This person is thought of as a trusted member of the organization. It should also be recognized that organizations have numerous categories of trusted individuals and use "role-based security" mechanisms to afford greater or lesser control to various individuals based on their respective roles. These may be thought of as concentric circles of access, but with overlap, according to one's need for access.

Second, insiders not only have access to and often control of systems and information, but they also are individuals who have a deep knowledge of their organizations' critical processes because of their dynamic involvement and experiences with these processes. Though this relationship may also exist between companies and their partners, this context is best typified by the employer–employee relationship. In this context, organizational policies and procedures may have an impact on the insider. Organizations seek to hire trustworthy employees. Firms implement SETA programs to train their employees in the use of proper actions and behaviors to ensure compliance with security policies. Managers may also utilize persuasive communications, such as fear appeals (Johnston and Warkentin, 2010), to encourage compliant protective behaviors. Sanctions may also be targeted against noncompliant employees as a deterrent (D'Arcy et al., 2009). Furthermore, the policies and actions of organizational managers can have a strong impact on the psychological perceptions of the employees, as well as their subsequent thought processes that may lead to various actions. Finally, these same principles apply also to former employees, customers, and partners, who often retain insider access and process knowledge and thus can pose continued threats even after the relationship is terminated or expired. The same factors that can influence insiders, presented in our three propositions, can continue to influence former employees. A recent survey of nearly 1900 firms from all major industries and from all over the globe found that 75% of respondents revealed their concern with the possible reprisal from employees recently separated from their organization (Ernst and Young, 2009).

Though extensive evidence suggests that insiders pose the greatest risk to information security (Brenner, 2009; CSO Magazine, 2007; Ernst and Young, 2009; Loveland and Lobel, 2010; Ponemon Institute, 2010; Richardson, 2011; Smith, 2009), many firms continue to spend the lion's share of their time, effort, and budget on perimeter security measures, such as firewalls, IDS, encryption of transmissions, anti-malware software, and content filtering, all of which aim to keep outsiders (e.g., hackers) or other external entities (e.g., malware) from penetrating the perimeter and threatening the organization's information resources. Though a certain degree of this focus is mandated by various regulations (Warkentin et al., 2011a), this allocation of resources is not entirely justifiable.

Behaviors that may result in harm to the organization are often unintentional. Prevention of these behaviors requires that employees be provided with knowledge regarding the behavior expected of them. This requirement is typically addressed through the development and implementation of ISP (Bulgurcu et al., 2010; Karjalainen and Siponen, 2011; Siponen and Vance, 2010; Thomson and von Solms, 1998). To further ensure employee compliance, information security instruction is often performed to explain the policies and achieve an understanding by employees regarding secure behavior (Puhakainen and Siponen, 2010; Siponen, 2000; Siponen and Iivari, 2006; Warkentin and Johnston, 2006; Warkentin et al., 2011a). However, employee compliance with ISP continues to be among the top concerns of organizations (Bulgurcu et al., 2010; D'Arcy and Hovav, 2009; Dodge et al., 2007; Kaplan, 2010; Loveland and Lobel, 2010; Prince, 2009). Therefore, information security research explores the typical controls used by organizations to encourage secure behaviors, such as SETA programs (D'Arcy et al., 2009; Furnell et al., 2002; Peltier, 2005; Wilson and Hash, 2003), development of acceptable use policies (Doherty et al., 2011; Ruighaver et al., 2010), and use of deterrence programs (D'Arcy et al., 2009; Straub and Welke, 1998).

* Security practitioners utilize access methods that require "something you know" (passwords, PINs), "something you have" (badges, cards, fobs), and/or "something you are" (biometric signatures such as fingerprints). So-called two-factor authentication is deemed better than methods that employ only one of these three.

Research of this nature historically looked at employee behaviors with the assumptions being that any unsecure behaviors were the result of non-malicious actions on the part of the employees. This assumption has changed over the past few years to include intentional and malicious actions. A continuum of employee intent as illustrated in Figure 54.1 has been identified and broadened the area of information security study.

On the upper end of the continuum, employee intent is passive and, on the whole, behavior is considered secure. The majority of the original insider threat research conducted would reside on this end as it focused on errors or misunderstandings as the underlying cause of unsecure actions or breaches in security. These types of unsecure behaviors may be corrected through improved information security instruction. In the middle of the continuum are intentional (but not malicious) acts and volitional behaviors such as choosing to not log off when leaving a PC unattended or to write down a password. These types of unsecure behaviors may be addressed through persuasion, deterrence, or other forms of behavioral controls. The lower end of the continuum includes intentional behaviors such as theft, embezzlement, and other deliberate actions. These behaviors are no longer benign in their intent and are committed for malicious reasons and or personal gain and are included in the category of crimes known as cybercrime.

The remainder of this manuscript identifies some theoretical tools for exploring InfoSec, along with a very brief assessment of the methods that have been used.

54.3 Theories Applied to Behavioral Information Security Research

The field of IS frequently adapts theories from other fields as is also the case with information security research. The majority of the research to date draws upon a small set of behavioral theories that originated primarily in the fields of psychology, sociology, communications, and criminology. These theories are listed in Table 54.1 along with a brief description and the primary literary sources for each.

Figure 54.2, generated by a word cloud software assessment of the key articles published in the area of IS security behaviors, provides a visual representation of the theories used to investigate such behaviors.

54.3.1 Deterrence Theory

Deterrence theory, commonly called general deterrence theory (GDT) though there are distinctions between general and specific deterrence that we will not address here, is identified as the theory most commonly applied in IS research (D'Arcy and Herath, 2011; Siponen et al., 2008). GDT provides the theoretical foundation necessary to explore and explain ISP compliance issues and IT abuse or misuse issues. Its foundation is the "rational choice model" of human behavior that posits that individual decisions are influenced by the fundamental motivation to apply a rational calculus of maximizing pleasure and minimizing pain. The assumption is that individuals will make behavioral choices based on the potential risks or costs and the potential gains or benefits, with the choice to act hinging on the balance between them. If the benefits are sufficiently large, a person may be willing to assume the risks or costs; but if the costs are sufficiently large, it will deter the behavior in question. Societies impose deterrence measures (costs of actions) in the form of punishments (fines or imprisonment) for illegal acts, whereas organizations impose deterrence measures against policy violations in the form of formal workplace sanctions, such as reprimands, demotions, withholding raises, or termination. These imposed costs are intended to discourage unwanted behavior. The theory states that if sanctions are in place, individuals will make a rational choice through the assessments of the likelihood of being caught (perceived sanction certainty), the harshness of the sanction or punishment (perceived sanction severity), and the speed with which the sanction may be carried out (perceived sanction celerity).

TABLE 54.1 Theories Used in Behavioral Research in Information Systems Security

Theory	Description	Primary Sources
General deterrence theory (GDT)	GDT states that individuals will weigh and balance the risks and gains associated with their actions and will consider the certainty, severity, and celerity of sanctions that exist to discourage the behavior	Gibbs (1975) Straub and Welke (1998)
Rational choice theory (RCT)	RCT states that individuals will make behavioral choices based on balancing the risks and gains of the choices available, and the level of magnitude of the risks and the gains are calculated through subjective individual assessment	Paternoster and Simpson (1996) McCarthy (2002)
Neutralization theory (NT)	NT states that individuals will use neutralization techniques to justify choices to perform behaviors even when the behaviors are not secure or are against policy	Sykes and Matza (1957) Klockars (1974) Minor (1981) Benson (1985) Cressey (1989) Siponen and Vance (2010)
Protection motivation theory (PMT)	PMT states that individuals will process fear appeals (persuasive messages) by performing a threat appraisal (severity and susceptibility of a threat) and a coping appraisal (response efficacy and self-efficacy), which will result in protection motivation behaviors	Rogers (1975) Maddux and Rogers (1983) Floyd et al. (2000)
Extended parallel process model (EPPM)	Related to PMT, the EPPM states that individuals, when presented with a high threat message, may become overwhelmed and will not develop protection motivation behaviors to respond to the threat but instead will develop avoidance behaviors and ignore or reject the threat	Witte (1992)
Elaboration likelihood model (ELM)	ELM states that individuals will process messages via a direct or peripheral route. A message processed via the direct route is more likely to result in stable and predictable outcomes whereas messages processed via the peripheral route are more likely to result in unstable and short-lived outcomes. A receiver's lack of personal involvement in the message topic and the availability of message cues may encourage peripheral route processing	Petty and Cacioppo (1986b)
Information manipulation theory (IMT)	IMT states that when individuals participate in a conversation, a message sender may deceive the other party, the receiver, through the subtle alteration(s) of one or more of the four main components of a message, namely the quantity, quality, clarity, or relevance of the message. The receiver of the message may be deceived if he or she does not detect the alteration(s)	McCornack (1992) McCornack et al. (1992)
Interpersonal deception theory (IDT)	IDT suggests that a sender knowingly wishing to deceive a receiver may strategically insert false information in the course of a conversation. The receiver will judge the credibility of the message and as long as no deception is detected the conversation may continue with the deceiver interactively adjusting the message as needed to remain undetected.	Buller and Burgoon (1996)
Equity theory (ET)	ET addresses human perceptions regarding inequality in social exchanges. The application of ET within organizational settings is known as distributed justice	Adams (1965)
Social cognitive theory (SCT)	Best known as the theory behind the self-efficacy construct, SCT provides a framework by which human behaviors may be predicted and explained through relationships between individuals and the environment	Bandura (1977)

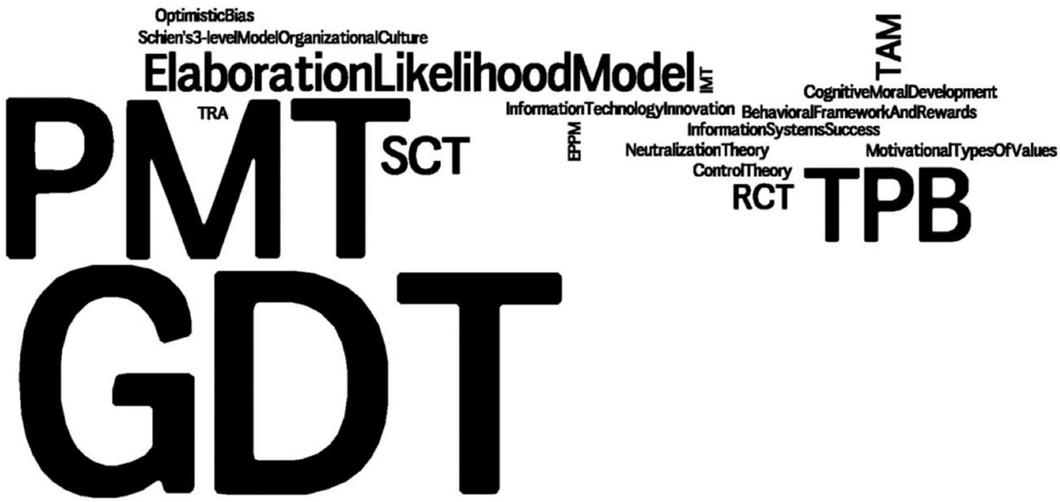

FIGURE 54.2 Visual representation of frequency of theory usage in IS security research.

The original form of GDT included only *formal* sanctions that carried legal consequences such as criminal penalties or civil lawsuits (analogous to workplace punishments). Theories about *informal* sanctions that were introduced by later scholars included those sanctions attributed to societal norms, such as guilt, shame, embarrassment, and social influence (Vance and Siponen, 2012). When moral individuals consider a deviant act, the mere thought of disapproval by one's peer group may deter the commission of the act, and thus informal sanctions likely play a very significant deterrence role, but they remain a largely unexplored antecedent of behavior in the InfoSec context.

The seminal work by Straub (1990) applied GDT within the field of IS and argued that the investments in information security must be balanced with the level of potential information asset risks. The focus was on the intentional human abuses and the common controls to discourage such abuses that were available at the time. The evolution of GDT and its use within IS saw the theory combined with Simon's managerial decision-making model to create the security action cycle (Straub and Welke, 1998), which became what is now the foundation for numerous information security research studies.

The security action cycle combines the generally accepted four stages of system risk reduction and identifies strategies for each where managers may implement security controls to reduce insider computer abuse (Straub and Welke, 1998). Security controls should first focus on *deterrence*, discouraging employees from performing unapproved, undesirable, and noncompliant behaviors. The goal is to minimize abuse; but if deterrence fails, the organization should implement *prevention* measures that inhibit risky employee behaviors that may bring harm to the organization's systems. Third, *detection* should be implemented in cases where employees are not deterred or prevented from behaving in an unsecure manner. Last, *remedies* should be implemented to enable recovery from any harm that may result from an employee's unsecure behavior, as well as punishment of the employee him/herself. GDT tells us that when the risk of being caught and punished outweighs the benefit of the action, individuals will refrain from performing the risky behavior. With this in mind, managers are encouraged to stress the deterrence and prevention security control implementation stages (Shropshire et al., 2010). The security action cycle has been recently expanded by Willison and Warkentin (2013) to look further back in time at the earliest motivations for workplace computer abuse, such as perceptions of organizational injustice, neutralization factors, and expressive motivations for committing abuse.

Information security studies focusing on the deterrence and prevention stages of the security action cycle often apply GDT toward assessing the effectiveness of various methods of information

security controls. These controls, termed "security countermeasures" (Straub and Welke, 1998), include both technical methods such as restricting system access through software authorization and behavioral methods such as implementation of SETA programs. While these studies find GDT to be useful overall, inconsistencies across study findings have led researchers to explore additional issues to better explain the effectiveness of security controls. For example, factors specific to an organization such as industry type, company size, and management support were explored and found to be important considerations toward security effectiveness perceptions (Kankanhalli et al., 2003).

Another study explored how the deterrent effectiveness of security countermeasures may be affected by the employees' awareness of the countermeasures (D'Arcy et al., 2009). Awareness was found to have a significant impact particularly through the perceptions of severity and certainty of the sanctions. The level of the employee's morality was also found to play a significant part in how sanctions are perceived (Dinev and Hu, 2007; Shropshire et al., 2012).

54.3.2 Rational Choice Theory

The most serious threats to information security assets may be classified as criminal acts. However, crimes committed within the workplace differ significantly from those upon which theories of criminology were based. The rational choice Theory (RCT) extends GDT and deterrence theory to be applied more generally toward the explanation of individual behaviors by noncriminals within the workplace (Paternoster and Simpson, 1996) and as such has been applied by IS researchers in the context of information security.

The assumption of RCT is that the choice to commit an offense requires that an individual perform an assessment of benefits and costs. When an individual determines that his or her perception of the benefits outweighs his or her perception of the costs, the choice to offend is more likely to be made. When applied to the context of employees and potential offenses committed within an organization, other factors such as business practices and culture are likely to influence the actions taken by individuals (Sabherwal and Robey, 1995). Therefore, perceived costs and benefits assessed may include those for the individual as well as for the employer. Furthermore, costs and benefits may be tangible, intangible, formal, and informal. The moral beliefs of an individual are also believed to be a strong contributing factor within RCT, with individual behaviors more strongly influenced by morality than by any fear of perceived sanctions (Paternoster and Simpson, 1996).

Although RCT's origins suggest an appropriate fit in the area of information security, IS researchers have only recently applied it within an information security context. For example, the costs and benefits of ISP compliance and costs of ISP noncompliance were the focus of a recent study that found RCT significantly explained the effects of an employee's beliefs regarding ISP compliance on the employee's secure behaviors (Bulgurcu et al., 2010). The assumption that moral beliefs are a significant predictor of an individual's behavior was supported within the context of information security (Hu et al., 2011). Along with moral beliefs, the effect of employee self-control was also explored and found that those with low self-control were more likely to commit noncompliant acts when the benefits were perceived to be higher than the perceived costs. In yet another study, once again moral beliefs were found to be significantly related to secure behavior choices, along with perceived benefits (Vance and Siponen, 2012) with higher moral beliefs positively related to ISP compliance intention and higher perceived benefits negatively related to ISP compliance intention.

54.3.3 Neutralization Theory

While GDT has been widely applied across information security studies, inconsistent results have been found and the explanation may lie with the neutralization theory (NT) (Benson, 1985; Cressey, 1989; Sykes and Matza, 1957). NT states that regardless of the values and norms to which an individual prescribes, a process to neutralize, or justify, breaking a rule may be performed when the individual desires

TABLE 54.2 Neutralization Techniques—Neutralization Theory

Technique	Description	Source
Appeal to higher loyalties	An act may be justified when the individual perceives that the act is required for those to whom he or she is loyal or must protect (family, friends)	Sykes and Matza (1957)
Condemnation of the condemners	An act may be justified when the individual perceives that those who condemn the act should themselves be condemned	
Denial of injury	An act may be justified when the individual perceives that no one was injured by the act	
Denial of responsibility	An act may be justified when the individual perceives that committing the act is beyond his or her control	
Denial of the victim	An act may be justified when the individual perceives that the act is a form of retaliation or that the party being injured deserves to be injured because he or she harmed others first	
Metaphor of the ledger	Individuals rationalize their misdeed by pointing to the many good deeds (or compliance) they have done in the past	Klockars (1974)
Defense of the necessity	Required actions, have no choice	Minor (1981)
Avoidance of greater harm	Various justifications	Garrett et al. (1989)
Comparative standards		
Legal rights		
Malicious intentions		
Claim of entitlement	Other rationalizations, some similar to earlier forms	Coleman (1994)
Defense of the necessity of the law		
Claim of individuality	Various justifications	Henry and Eaton (1994)
Claim of relative acceptability		
Justification by comparison	Individuals justify committing the act because it is less harmful than other acts that could be just as easily committed	Cromwell and Thurman (2003)
Postponement	In order to commit the act, individuals put off any thoughts of wrong or right or of guilt feelings about committing the act	

Source: Adapted from Willison, R. and Warkentin, M., *MIS Quarterly,* 37, 1, 2013.

the outcome believed to be attainable by performing the action (Siponen and Vance, 2010). The use of neutralization techniques may explain why individuals behave in an unsecure manner and risk harm to organizational assets. The theory originally proposed that five neutralization techniques exist (Sykes and Matza, 1957) and included denial of responsibility, denial of injury, denial of the victim, condemnation of the condemners, and appeal to higher loyalties. A sixth technique, the metaphor of the ledger, was added about 20 years later (Klockars, 1974) and a seventh, the defense of necessity, was added soon after that (Minor, 1981). Several other neutralization techniques have been identified and are listed in Table 54.2 with the original five techniques with a brief description of selected entries.

54.3.4 Protection Motivation Theory

The study of persuasion and its effects on individual behavior has recently gained popularity with information security researchers in the field of IS. The use of persuasive messages known as fear appeals and the resulting effects of the messages on the attitudes and behaviors of individuals first gained the interest

of researchers in the field of psychology during the 1950s (Janis and Feshbach, 1953, 1954). The numerous research projects produced findings that indicated further research was worthwhile, but the explanations of the findings lacked a cohesive theory until 1975 when the protection motivation theory (PMT) was developed (Rogers, 1975). In the years following, researchers in other fields such as communications (Witte, 1992), health care (Kline and Mattson, 2000), marketing (Dillard and Anderson, 2004), and IS security (Anderson and Agarwal, 2010; Herath and Rao, 2009; Johnston and Warkentin, 2010) continued the exploration of the ability of fear appeals to stimulate the appropriate level of fear or concern about an event and change individual attitudes or behaviors. Fear appeals have been shown to be effective in encouraging individual behaviors in the areas of health promotion, societal defense, and information security.

The PMT states that when individuals are exposed to a fear appeal, two cognitive mediating processes will ensue and protection motivation behavior will result. The cognitive mediating processes are the appraisal of the threat and the appraisal of the individual's capacity to cope with the threat. Threat appraisal includes the constructs of perceived threat severity and perceived threat susceptibility. Coping appraisal includes the constructs of perceived response efficacy and perceived self-efficacy. For the fear appeal message to be effective, it must include appropriate details regarding the threat and the recommended response to a threat, specifically that the threat is severe and is likely to occur, and a response that works is available and can be successfully performed (Maddux and Rogers, 1983; Rogers, 1975). When exposed to a fear appeal message, individuals perform threat and coping appraisals, and the individual's perception of the level of threat severity, threat susceptibility, response efficacy, and self-efficacy will affect the level of protection motivation behavior developed. If the threat is perceived to be serious and likely to occur, the recommended response is perceived to be effective against the threat, and the receiver believes he or she is capable of successfully performing the response, motivation toward protective behavior will result.

PMT has been applied in several contexts within the area of information security. Findings in most studies indicate use of PMT is effective toward explaining information security phenomena, but the findings have not been consistent across all contexts. For example, numerous information security threats exist with online activities such as sharing information on social networking sites, participating in blogging, and frequenting any password-secured website (Banks et al., 2010; LaRose et al., 2005, 2008; Marett et al., 2011; Zhang and McDowell, 2009). In the context of social networking, individuals' decisions whether to share personal information were influenced the most by the threat appraisal variables (Marett et al., 2011) along with social influence (Banks et al., 2010). Alternately, when considering overall online safety, the greater influence was found to be self-efficacy and response efficacy (LaRose et al., 2008). Similarly, self-efficacy and response efficacy were found to be strong influences toward online account password management intent along with a strong negative relationship between response cost and intent to implement strong passwords (Zhang and McDowell, 2009).

Other areas of information security research with PMT include explorations of general secure computing practices (Anderson and Agarwal, 2010; Ng et al., 2009; Woon et al., 2005; Workman et al., 2008) and anti-malware software use (Garung et al., 2009; Johnston and Warkentin, 2010; Lee and Larsen, 2009; Liang and Xue, 2010; Stafford and Poston, 2010). Application of PMT within these contexts has also produced varied results. For example, social influence, self-efficacy, and response efficacy were found to be the strongest influences of intent to use anti-malware software in one study (Johnston and Warkentin, 2010). Another study found that threat severity, self-efficacy, and response efficacy were significant indicators of software use, and also found that threat vulnerability and response costs produced no significant contributions (Garung et al., 2009). Particularly interesting results have been found as well, such as relationships between threat severity and self-efficacy and threat severity and response efficacy (Johnston and Warkentin, 2010), two relationships that are generally not tested in PMT-based information security research.

Another common information security threat is related to the great amounts of data being generated each day and the threat of losing the data at any time. A simple response to this threat is to perform data backups. Self-efficacy and response efficacy were found to be positively related, and threat susceptibility

and severity were found to be negatively related to performing data backups (Crossler, 2010). Another study, however, found that only threat severity, response efficacy, and self-efficacy were strong indicators of behavioral intent (Malimage and Warkentin, 2010).

PMT research in the context of information security has produced different and varied findings as compared to the prior PMT research in contexts such as health care and marketing. Constructs that are not included in prior PMT research have shown to be strong indicators of secure behavior intent within an information security context, suggesting that the PMT model may require expanding to better fit this context. For example, social influence has been found to be highly significant toward influencing security behaviors (Johnston and Warkentin, 2010; Pahnila et al., 2007a) and descriptive norms have been found to be particularly important in influencing protective behaviors against a collective threat, with subjective norms found to be influential against individual threats (Anderson and Agarwal, 2010).

54.3.5 Extended Parallel Process Model

At times, research has found that certain fear appeals may not produce adaptive (protection motivation) behaviors, but instead produce maladaptive behaviors. A theory developed to explain such results is the extended parallel process model (EPPM) (Vroom and von Solms, 2004; Witte, 1992). EPPM states that fear appeal theories assume message acceptance and therefore only explain behaviors that result from acceptance of the persuasive message. For example, when the threat appraisal is high and not properly balanced with a high coping appraisal, an individual may become overwhelmed by the threat and choose to reject the persuasive message and develop maladaptive avoidance behaviors rather than adaptive protection motivation behaviors. In these unbalanced cases, rather than achieving the intended outcome of the message with acceptance of the persuasion and ensuing adoption of protection motivation behaviors, the outcome may be *defensive avoidance* where the individual responds by avoiding the appeal by choosing to ignore the message or avoid thinking about the threat. Or it may be *reactance* where the individual negatively reacts to the appeal, choosing instead to behave oppositely in a phenomenon called the "boomerang effect." In either case, individuals with insufficient coping levels, either response efficacy ("it won't work") or self-efficacy ("I can't do it"), will exhibit undesirable maladaptive responses that manage the fear itself, rather than the threat. Message rejection is a common phenomenon in which a user suggests that the message is not valid and that the threat is not severe. In the context of information security threats, a user may suggest that reports about viruses are overblown and he or she should not worry about them ("head in the sand" reaction). Or the message recipient may reject the messenger, discrediting the validity of the appeal. EPPM, like PMT, also states that when presented with a fear appeal, an individual will perform two message appraisals. However, rather than the appraisals being those of threat and coping as in PMT, EPPM describes a cognitive process to determine the danger control (which includes threat and coping appraisals) and an emotional process to determine the fear control (Vroom and von Solms, 2004; Witte, 1992).

54.3.6 Elaboration Likelihood Model

A theory that addresses the cognitive processes that individuals perform when presented with information is the elaboration likelihood model (ELM) (Petty and Cacioppo, 1986a,b). The theory states that there are two possible routes from which individuals will choose to process a message: the central route and the peripheral route. The general goal of a persuasive message is to achieve a long-term change in the attitude or behavior of an individual. When a message is processed by way of the central route, a more predictable and stable change of attitude or behavior typically results. When processed by way of the peripheral route, however, the results tend to be unstable and short-lived. Therefore, persuasive messages will be more successful when processed via the central route.

When an individual is confronted with a message that he or she is not motivated to directly process, peripheral route processing may offer a more comfortable "path of least resistance" for them.

For example, an individual may choose the peripheral route to process a message that is too difficult to process, that is not interesting, or that is a subject with which the individual is not comfortable. A message that is processed through the peripheral route relies upon message cues that may be found within or around the message. Cues may be perceptions about the sender of the message such as his or her likability, trustworthiness, or level of authority, or the presentation of the message such as its attractiveness or form of communication media. Rather than spending the cognitive effort toward fully addressing the message, individuals may instead rely on message cues to influence the decisions regarding the message.

Messages processed via the central route will be predictably and more fully processed for maximum understanding. ELM states that to discourage peripheral route processing, a message must be developed with no unnecessary cues that may be used to encourage the peripheral route and must include features that will motivate individuals to process it through the central route. Therefore, knowledge and understanding of these two potential processing routes can aid in the development of a persuasive message to ensure that individuals process the message by way of the direct route such that there is a greater likelihood that an intended and longer-lasting outcome is achieved.

ISP instructional programs may benefit from ELM by concentrating on modeling instructional messages to encourage central route processing and avoiding potential message cues that may encourage peripheral route processing (Puhakainen and Siponen, 2010). This includes developing the programs to ensure that individuals are motivated to expend the cognitive effort to fully process the messages such that longer-lasting behavior change may occur. Concentrating on providing ISP instruction that is relevant and meaningful to individuals has been found to be successful in encouraging employee ISP compliance.

ISP compliance involves numerous information security issues. An increasingly growing threat involves techniques of social engineering used by persons wishing to gain access to systems to which they are not authorized. The social engineering techniques use deceptive communications and encourage individuals to process messages via the peripheral route (Workman, 2007, 2008). When a perpetrator uses social engineering, employees are fooled into performing an act or revealing sensitive information to the perpetrator. Most ISP instructional programs teach employees to be ethical and responsible and to protect information assets but do not prepare them to fend off techniques such as social engineering. ISP instructional programs may benefit from the inclusion of instructional methods for employees to recognize and prevent social engineering attacks.

54.3.7 Information Manipulation Theory

Originating in the field of communications, the information manipulation theory (IMT) (McCornack, 1992; McCornack et al., 1992) has recently been applied to information security research. The theory builds upon conversational theory that states individuals have expectations regarding the quantity, quality, clarity, and relevance of the information transmitted by a conversation. IMT proposes that any or all of these four expectations may be manipulated by the sender in such a way that the receiver of the message is unaware of the manipulation and the sender is then able to deceive the receiver. This can also be stated to mean that the level of deceptiveness of a message may be identified through quantifiable means through measurement of the quantity, quality, manner, and relevance of the information contained in the message.

54.3.8 Interpersonal Deception Theory

Another theory from the field of communications and one gaining interest within information security literature is the interpersonal deception theory (IDT) (Buller and Burgoon, 1996). As with IMT, IDT is built on conversational theory and involves a sender knowingly attempting to deceive receivers, but is expanded to include the receivers' attempts to process the messages and to verify the truthfulness of the messages. IDT states that an interpersonal communication involves two or more individuals

dynamically exchanging information. The assumptions of IDT are that communicators enact both strategic and nonstrategic behaviors while encoding and decoding messages. Throughout the conversation, the credibility of the sender and of the message is judged by the receiver. The progression of the conversation is interactive and continuing. A deceiver may strategically insert false information into a conversation and then observe the reaction of the receivers to determine whether or not the deception was recognized. If the deception is not discovered, the conversation continues with the deceiver continuing to insert false information, adjusting as needed to remain undetected. As the conversation continues, familiarity increases and truth biases become stronger, resulting in a situation ripe for abuse. Such exchanges occur in face-to-face so-called social engineering security threats in which an individual tricks another party into revealing sensitive information, such as a password. These exchanges also frequently occur in the virtual space, where emails and websites (such as so-called fake AV sites) deceive individuals into disclosing protected information or into downloading malware in the guise of anti-virus software. Deception plays a large role in the behavioral threat environment, and is receiving fresh attention from scholars.

54.3.9 Equity Theory

The seminal work to advance the equity theory (ET) was conducted by Adams (1965) in which individuals' perceptions of fairness within social exchanges were explored. The application of ET to equity perceptions by employees within organization has become known as distributive justice (Nowakowski and Conlon, 2005). For example, employee pay scales, raises, benefits, and hiring practices are all issues where employees may compare themselves to their coworkers and the potential for perceptions of inequality exists. In those instances when there are such perceptions, employees may become disgruntled and in turn behave in ways that are not beneficial to the organization. Employees are known to be the insider threat to organizations and information security, and the worst cases of employee disgruntlement may result in attempts by employees to harm the organization's information assets. A large percentage of the reported organizational computer abuses have been attributed to employee grievances, suggesting that this is a worthy area of study within information security, yet to date only a few works have addressed information security from this organizational aspect (Willison and Warkentin, 2009, 2013).

A larger domain known as organizational justice includes four constructs in total to describe the various forms of inequality perceptions that employees may develop within a workplace. With the first being distributive justice, second is procedural justice, related to inequalities an employee may perceive to exist within the organizational procedures (Leventhal, 1980; Leventhal et al., 1980). The last two are interactional justice, also known as interpersonal justice, and information justice (Greenberg, 1990, 1993). Interactional justice is related to the interactions between authority figures and their subordinates. Informational justice is related to the completeness and accuracy of the information as it is disseminated from senior members of the organization down through those more junior employees.

54.3.10 Social Cognitive Theory

The social cognitive theory (SCT) provides a framework to explain and predict individual behavior and changes to behaviors through the interaction of an individual with his or her environment (Bandura, 1977). SCT is primarily known as the theory behind the construct of self-efficacy and has been included in numerous studies in the field of IS with the most prominent being the development of the computer self-efficacy construct (Compeau and Higgins, 1995; Marakas et al., 1998). A self-efficacy construct is frequently included in studies within the information security context, most often addressing questions related to ISP compliance (Bulgurcu et al., 2010; Pahnila et al., 2007b). Studies based on the theoretical foundation of PMT (Anderson and Agarwal, 2010; Herath and Rao, 2009; Johnston and Warkentin, 2010), a theory that includes the self-efficacy construct, are perhaps the most common studies found within the context of information security to also rely on SCT.

54.4 Methods Applied to Behavioral Information Systems Security Research

The previous section described the theories used to investigate the research questions explored in the context of individual security-related behaviors, as well as some of the findings from research today. This section very briefly describes some of the methods commonly used in this domain. As expected, the methods are similar to other behavioral research about individual users within the IS context. InfoSec researchers survey individuals about their perceptions, attitudes, and beliefs, as well as their behaviors or intentions to exhibit various behaviors. Scholars have also devised creative lab and field experiments to create environments in which to measure salient constructs that relate various factors to security behavior. However, several unique characteristics about these behaviors and their motivation present unique challenges to valid data collection.

Measuring actual user behavior is the "holy grail" of IS behavioral research, and we often rely on measuring self-reported behavioral intention to act in a specific manner. In InfoSec, we often ask individuals to report their intention to act in a protective manner, to comply with organizationally mandated policies and procedures, or to violate such policies. Beyond the traditional concerns about validity threats from common method bias or social desirability bias, there are unique challenges encountered when asking an individual about committing a crime, which have been addressed by the criminology scientific community, from which we draw our inspiration. (Similar resistance is encountered when asking employees about violation of organizational policies.) One common solution is the implementation of a scenario-based factorial survey method approach, in which subjects are asked to read one or more versions of a scenario in which statements are embedded that represent various levels or values for the independent variables. The scenario character, acting in response to these antecedents, chooses to act in a deviant manner by violating a social norm, law, or organizational policy. The subject is then asked about the likelihood of doing as the scenario character did. In this way, the subject disassociates himself or herself from his or her own moral obligations to a certain extent and will provide a more valid indication of his or her behavioral intent. This method is now used widely within IS security behavior research to investigate the cognitive and affective elements of interest. In other cases, researchers have found creative ways to collect actual behaviors from server logs, from managers, and from other sources (Warkentin et al., 2011b, 2012).

54.5 Conclusions

Recent research in behavioral InfoSec has surfaced extensive knowledge about human behavior within this domain; however, many questions are left unanswered and much work remains. Scholars are beginning to explore new factors and new interpretations of the motivations and other antecedents of human behavior in this context, and more insights are gained every year. Future work in this area is informed by scholarly assessments of this domain (c.f. Willison and Warkentin, 2013 and Crossler et al., 2013) and by the real-world evidence of new threats and new psychological factors at play.

Privacy, Accuracy, and Accessibility of Digital Business

Ryan T. Wright
University of Massachusetts—Amherst

David W. Wilson
University of Arizona

55.1 Introduction

Today's society has been transformed by our ability to do business anywhere using just about any device with Internet connectivity. Digital business refers to the capabilities that make it possible to access information and transact using ubiquitous technologies enabled by the digitization of processes, documents, and services. Technologies facilitating digital business such as cloud computing and mobile access have changed how organizations offer access to information by allowing employees and customers to increase efficiency and task satisfaction by using online tools. As the technology behind digital business has become more and more complex and access become more and more available, severe problems with the security of these systems have emerged.

Many CEOs have ranked security and privacy above financial concerns for their organizations (Boltz 2011). This is not surprising given the publicity surrounding the alleged illicit access to private and sensitive information by several large companies with a strong presence in digital business. Information privacy has also been a major societal/government issue as politicians struggle to protect utility infrastructures that are run using Internet technologies (Bartz 2012). Examining the impact of IT security breaches on privacy, it is evident that this problem is pervasive for both consumers and organizations. For example, Langevin reported that in 2010 cyber-attacks on private information cost nearly $8 billion in the United States (Langevin 2011). Further, over 8 million U.S. residents have been victims

of identity theft due to digital attacks (Langevin 2011). It is clear that information privacy is a serious issue for individuals, organizations, and society in general.

There are typically two pillars to combating digital privacy threats. First, we use security technology (e.g., specialized software) to combat attacking technology (e.g., viruses). The Internet environment has been defended for many years by security systems such as firewalls, virtual private network (VPNs), intrusion detection systems, and so on. On the other hand, the human component of protecting organizations' and individuals' privacy looms as an even larger problem. Even the most sophisticated IT security systems can be easily thwarted by human error, incorrect usage, or malicious actions. For example, it was discovered that the Texas government had the private information of over 3 million state workers exposed on the Internet for over a year due to human error (Shannon 2011). Further, in October of 2010 Microsoft servers were commandeered and misused by spammers to promote more than 1000 fraudulent pharmaceutical websites (McMillan 2010). Employee misuse of the systems was again blamed for this security breach.

It is clear that regardless of the technology, the human aspect of information privacy protection remains central in understanding and controlling against breaches, attacks, and misuse. The information systems (IS) discipline should be the right place to address the human–technology–business concerns. IS typically is the interface between business and IT. By providing an understanding of how humans interface with the technology, we can provide a foundation that may help curb information privacy issues. For this reason, the goal of this chapter is to provide a framework to understand the contemporary literature surrounding IS privacy, which is closely tied to the issues of security, and provide a roadmap for future efforts in understanding this important problem of information privacy that threatens digital business. The chapter will focus on the behavioral (as opposed to technical) issues being addressed by IS researchers in the privacy domain.

The chapter will unfold as follows. First, we will define and examine the interplay between information privacy and security. Next, we will provide a foundation for understanding privacy at the individual level. This is then followed by outlining the organizational-level privacy issues. Finally, we will provide a roadmap for future research on privacy and security using the IS research lens.

55.2 Defining IS Privacy and Security

It is difficult to explore issues regarding information privacy without discussing security. Many scholars have argued that privacy and security are integrated and are difficult to tease apart (Chan et al. 2005). To this point, Fair Information Practices have been developed that include the intersection of privacy and security. These global principles are guidelines to balance privacy concerns with organizations' interests (see Table 55.1). This section focuses on the important and significant relationship between privacy and security.

TABLE 55.1 Fair Information Practices

Fair Information Practice	Purpose	Example
Notice	To alert customers to the gathering of their personal information	Your information is collected so we can offer you appropriate goods and services
Choice	To extend to customers the ability to choose whether their information is tracked, used, and reused	You can choose not to receive e-mails that provide information about sales promotions
Access	To offer customers access to their personal files to allow them to request that inaccurate information is corrected	You can request the ability to view your file and make any necessary corrections
Security	To assure customers that their information cannot be accessed by any persons other than those authorized by the organization	We encrypt all information and store it on our secure servers

Source: Chan, Y.E. et al., *Comm. Assoc. Inform. Syst.*, 16(12), 270, 2005.

Companies and individuals have private digital information that they wish to protect from unauthorized access, tampering, corruption, or unplanned disasters. The provision of this protection is referred to as security or, more specifically, information security. The concept of information privacy is rooted in the view that privacy consists of an individual's control of access to the self (Altman 1975). Accordingly, most modern definitions of information privacy equate privacy with the ability to control one's private information and others' access thereto (Smith et al. 2011). A fairly comprehensive definition of this form of privacy is provided by Margulis (1977, p. 10): "Privacy… represents the control of transactions between person(s) and other(s), the ultimate aim of which is to enhance autonomy and/or to minimize vulnerability."

In the early 2000s, marketing organizations started categorizing end users based on their inherent privacy beliefs (Harris Interactive and Westin 2002). Overall, there are three basic categories:

1. Privacy fundamentalists are the users who do not see any benefit in disclosing any personal or sensitive information. These users are extremely careful of their digital information. According to Harris Interactive, this makes up about 25% of the U.S. population.
2. Privacy pragmatists are those users who undertake a cost–benefit analysis to the collect of their personal information. These users evaluate how organizations are going to use their data and weigh this use with the value of the service. The pragmatists often use cognitive economics risk–reward models to help with their decisions. Harris Interactive predicts that about 55% of the U.S. population consists of privacy pragmatists.
3. Privacy unworried are users who are unconcerned in general with how organizations use their personal information. This group generally rejects others' view that there are concerns with personal information. Harris Interaction classifies about 20% of the U.S. population as unworried.

Companies' and individuals' need for security is driven by a desire for one of several privacy concerns, though the relationship between privacy and security is debated in the literature (Belanger et al. 2002). Culnan and Williams (2009) argue that even when organizations take sufficient precautions in protecting personal information (thus providing information security), they might still engage in or permit unauthorized use of that information, which violates users' information privacy. Thus, as Ackerman (2004) states, "security is necessary for privacy, but security is not sufficient to safeguard against subsequent use, to minimize the risk of… disclosure, or to reassure users" (p. 432, cf. Smith et al. 2011). The next section will outline the mechanisms used to understand a user's expectations for security and privacy.

55.2.1 Protecting Users

Protecting users' privacy with security measures is the nexus of understanding both security and privacy issues. This protection is accomplished through providing three security assurances to the end users of an IS: (1) integrity, (2) confidentiality, and (3) authentication (Smith et al. 2011). Taken together, the security assurances provide a framework for end users and organizations to understand the mechanics involved in information security. Since our focus is on the human factors involved in protecting users' privacy, we will break down each assurance in terms of possible threats and opportunities for knowledge advancement (See Table 55.2). In order to do so, we will integrate Smith et al.'s conceptualization of security assurances with Smith et al.'s (1996) research on an individual's information privacy concerns or concern for information privacy (CFIP).

Smith et al.'s (2011) conceptualization of security can be likened to an onion where each assurance is based on the previous order of assurance. Core to the assurance model is integrity. The next layer is confidentiality and finally authentication. With this layered approach, in order to create problems with one of the assurances, the previous assurance must be compromised. For example, if the confidentiality of the private information is inappropriately leaked, first authentication must have been compromised. This is a general rule of thumb when conceptualizing how security threats affect the assurances (see Figure 55.1).

TABLE 55.2 Understanding Privacy Concerns and Security Assurances

Privacy Concerns	Definition	Human Threats	Security Assurance
Collection errors	Provides assurance that information is not altered during transit or storage	Information accuracy Information reliability	Integrity
Secondary use	Ensures that information is disclosed only to authorized individuals and for authorized purposes	Information property	Confidentiality
Unauthorized access	Provides verification of one's identity and permission to access a given piece of information	Information accessibility	Authentication

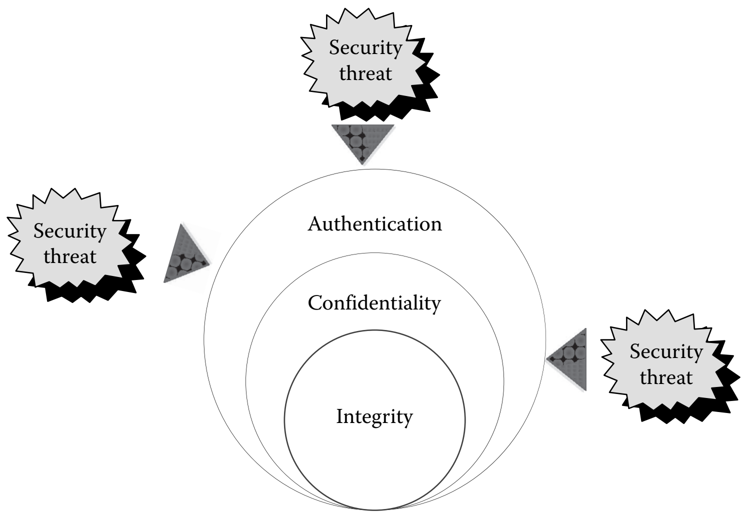

FIGURE 55.1 Relationship between security assurances.

The following section discusses the ways in which the three security assurances provide protection of users' private information. We discuss each of the aspects of Stewart and Segars' (2002) information privacy concerns research. These concerns are summarized in the first column of Table 55.1, which also includes definitions and human threats for each of the three categories of privacy concerns. Table 55.1 also maps these privacy concerns to each of the three security assurances illustrated in Figure 55.1. We now proceed to discuss each grouping of privacy concerns and security assurances in turn, addressing first the privacy concerns, then explaining the related security assurance.

55.2.2 Privacy: Collection and Errors

The collection and accuracy of private information are one potential source of users' concerns regarding information privacy (Stewart and Segars 2002). The act of collecting private information inherently reduces an individual's control over that information, since the individual no longer has direct oversight regarding the information collected. Collection concerns focus on both the amount of personal information being collected and how the information is being stored (Culnan and Bies 2003; Malhotra et al. 2004a). Error concerns are based on the protection against deliberate and accidental error in personal data (Smith et al. 1996). Though the Smith et al. (1996) model separates collection and information errors, these two are often discussed together since most errors in IS take

place during a collection process (Clouse et al. 2010). And, in the context of our security assurance framework, both collecting private information and ensuring that it is free from error are related to integrity, as discussed next.

55.2.3 Security: Integrity

Integrity provides assurance that collected private information is not altered during transit or storage. There are two significant human threats associated with integrity. The first threat associated with human interactions is information accuracy. Information accuracy entails ensuring that the fidelity of information stays intact. Security issues often occur when users (or hackers) change data. Hospitals are often faced with accuracy problems as small changes by medical staff in electronic medical records can cause major patient problems and even result in death (Cliff 2012). The second factor that can be manipulated by humans is information reliability. Information reliability is a product of how the users view the information provided by a system. In many instances, we have seen a user question the system's reliability and therefore ignore system requests or system information when making important decisions. One such example is seen in research done on Microsoft's anti-phishing toolbar (Wu et al. 2006). In this study, it was shown that the information provided by the system—in this case the anti-phishing toolbar—was unreliable less than 10% of the time. However, this unreliable information caused users to disregard the information provided by the tool altogether, causing a security threat.

55.2.4 Privacy: Secondary Use

The application of confidentiality in privacy is mainly concerned with the secondary use of data. This may include selling of personal information, marketing using personal information, using personal information to make business decisions, and so on. Although explicit research on secondary use of information is scant, there has been a great deal of popular press about this issue. For example, in late 2011 Google changed their data privacy statement (Garside 2012). This change in policy gained much attention, as Google owns a lot of personal information about their users. It is clear that Google benefits when aggregating personal information from their different businesses. For example, Google can aggregate private information about which videos a user watches from YouTube with geo-location information from their Android phone while scanning the user's Gmail account for certain key words. Using this aggregated data Google can clearly distinguish market segments at a very fine level of detail.

The concerns of users regarding tracking of their online behavior have caused government bodies to start regulating the use of tracking technology such as "cookies," which are text files used to track Internet browsing behavior. In one such case, the European Union's 2011 online privacy law now makes it very difficult for marketers to capture users' information by directing online companies such as Microsoft and Google to add a "do not track" button to their web browsing software (Enright 2012).

There are two main points of emphasis when addressing privacy concerns surrounding secondary use. First is the issue of control by the user of information access by other parties. Control in this instance means that users desire control over who sees what particular piece of personal information. For example, the "do not track" button on browsers allows users to control which information is captured. The second issue is awareness (what Chan et al. 2005 classify as "Notice"). Awareness is the individual's desire to be accurately informed regarding the extent to which the organization shares his or her personal information with third parties. One of the biggest issues for consumers is whether the organization will be allowed to sell this personal information to interested third parties. Being in control and aware in order to reduce users' concerns regarding secondary use requires that organizations manage confidentiality.

55.2.5 Security: Confidentiality

Confidentiality ensures that information is disclosed only to authorized individuals and for authorized purposes. The research around confidentiality in general is difficult to execute due to its sensitive nature. The core threat issue has to do with information property. Information property focuses on who owns the personal information and how this information can be exchanged (Litman 2000).

55.2.6 Privacy: Unauthorized Access

It is clear that access to information is critical to knowledge workers and decision makers in an organization. However, unlimited access to information is a concern as it increases the likelihood of breaches, leaks, and misuse of private information (Malhotra et al. 2004a). As with most security decisions, and as previously mentioned, there is commonly a risk–reward decision pertaining to privacy. With authentication and control these questions are as follows:

1. Who should access the information?
2. For what purpose do they need access?
3. How is this information being used?
4. When do they need access to this information?

These questions most definitively are associated with privacy concerns. Privacy concerns about improper access include trepidations that personal data are readily available to users that are not authorized to access, use, or disclose the personal information (Smith et al. 1996). Understanding users' desire for protection against unauthorized access to private information is a critical security issue that needs to be addressed by the IS authentication process.

55.2.7 Security: Authentication

Authentication provides verification of one's identity and permission to access a given piece of information. Authentication is sometimes seen as a mechanical process whereby a system either provides access or not. Authentication processes are typically set by policies and business rules and enforced by automated systems to provide access to personal or sensitive information. The concept of users' accessibility is the human threat in this assurance category. The concept of information accessibility has been around since the early 1980s. Information accessibility is defined as what information a person or organization has the right to obtain about others and how this information can be accessed and used (Culnan 1984). Accessibility, which is enforced by authentication, is a critical issue for IS managers. Seminal research has posited a positive relationship between perceived accessibility of information and the information use (Culnan and Armstrong 1999).

The next two sections will build on the privacy concerns and security assurances explored earlier to give some guidance on how individual behaviors can influence security behavior. This is followed by scrutinizing how these individual behaviors influence organizational policies and procedures.

55.3 Privacy Behaviors

As the pivotal factor in considering information privacy, humans have been the object of a plethora of privacy and security research and theories in the IS discipline. Organizational policy and outcomes are undoubtedly linked to individual behaviors. Thus, we first synthesize and summarize the literature concerning individual behavior related to information privacy and security. These topics and sample studies are summarized in Table 55.3.

TABLE 55.3 Privacy, Security, and Individual Behavior Theories

Theories	Description	Sample Studies
Trust and risk literature	Common constructs included in theories modeling individual security and privacy behavior. These serve to facilitate or inhibit secure behavior and/or information disclosure	*Trust and distrust* (Gefen et al. 2008; McKnight and Choudhury 2006; McKnight et al. 2002) *Risks* (Dinev and Hart 2006; Featherman and Pavlou 2003; Gabrieal and Nyshadham 2008; Pavlou and Gefen 2004) *Privacy concerns* (Malhotra et al. 2004a; Smith et al. 1996; Xu et al. 2011)
Protection-motivation theory	Self-protection theory adapted from the health behavior domain, which argues that secure behavior is motivated by perceptions of vulnerability, severity of threat, and the effectiveness or efficacy of secure behavior	(Herath and Rao 2009b; Johnston and Warkentin 2010; Lee and Larsen 2009; Ng et al. 2009)
Deterrence theory	Theory adapted from criminology that predicts the effectiveness of sanctions on users' secure behavior. The theory generally concerns a sanction's severity and certainty	(D'Arcy et al. 2009; Harrington 1996; Herath and Rao 2009a; Kankanhalli et al. 2003; Pahnila et al. 2007; Straub 1990)
Neutralization/rational choice	Theoretical lens that accounts for users who justify or neutralize their insecure behavior and/or rationally decide to behave insecurely after weighing the costs and benefits of secure behavior	(Li et al. 2010; Siponen and Vance 2010)
Theory of planned behavior	Common cross-disciplinary theory that predicts a person's behavior according to behavioral intentions, which are influenced by attitudes, social norms, and perceptions of self-efficacy or behavioral control. This has been used as a framework to explain different aspects of security compliance and other individual behaviors	(Ajzen 1991; Bulgurcu et al. 2010; Dinev and Hu 2007)
Privacy disclosure	Rich stream of literature that investigates privacy disclosure behavior, both from the perspective of the organization trying to encourage disclosure for marketing and other purposes and from the perspective of the user who would rather not disclose much information in order to protect privacy	(Acquisti and Grossklags 2005a; Chellappa and Sin 2005; Li et al. 2011; Lu et al. 2004; Malhotra et al. 2004a; Smith et al. 1996; Tsai et al. 2011; Xu et al. 2011)

55.3.1 Theories about Perceptual Beliefs

Much of the IS literature that surrounds privacy and security has been based on individuals' perceptions of certain behaviors that have been developed in conjunction with privacy and security theories. Some examples of research questions about individuals' perceptions are as follows: (1) Do you trust people online (McKnight et al. 2011)? (2) How private do you need to keep your sensitive information (Dinev and Hart 2004, 2006)? (3) How concerned are you about disclosing personal information (Malhotra et al. 2004b)? All of this research uses an individual lens of analysis to understand how users' beliefs impact their interactions with technology systems such as

e-commerce, enterprise resource planning (ERP), and so on. The following will outline the three main theoretical perspectives and their respective individual-level behavioral perceptions related to privacy.

55.3.1.1 Risks

In the context of privacy, risk has been defined as "the degree to which an individual believes that a high potential for loss is associated with the release of personal information to a firm" (Smith et al. 2011, p. 13). Perceived risks are often characterized as one's sense of control over their personal information (Featherman and Pavlou 2003), or the general beliefs one has about the likelihood of organizations sharing that information (whether intentionally or through insufficient security precautions) with unauthorized third parties (Dinev and Hart 2006). Risks can either be associated with a specific transaction or transaction partner (Li et al. 2011; Slyke et al. 2006) or can refer to a general measure of risks associated with transacting via the Internet (Dinev and Hart 2006; Gabrieal and Nyshadham 2008). When the likelihood of unauthorized sharing or security breaches is perceived to be high, individuals tend to report higher privacy-related concerns (Dinev and Hart 2004, 2006), are less trusting of the organization (Pavlou and Gefen 2004), and are accordingly less willing to conduct transactions with that organization (Pavlou and Gefen 2004).

55.3.1.2 Concerns

Closely related to privacy and security risks, privacy concerns reflect users' worries about the potential loss of information privacy (Xu et al. 2011). Just as with privacy risks, privacy concerns have been framed both at the general level reflecting broad concerns about electronic transactions (Dinev and Hart 2006; Li et al. 2011; Slyke et al. 2006) and at the situation level representing specific concerns about a given transaction or transaction partner (Xu et al. 2011). Privacy concerns have become the default measurement proxy for measuring users' beliefs or attitudes about privacy in general (Smith et al. 2011). Not surprisingly, individuals who report higher privacy concerns, either at the general or at the specific level, perceive privacy risks to be higher (Li et al. 2011; Malhotra et al. 2004a) and are less willing to engage in transactions via the Internet (Dinev and Hart 2006).

55.3.1.3 Trust

Underlying several of the concepts in this section, trust has been validated as key in facilitating online interactions, both in e-commerce (McKnight et al. 2002) and other (e.g., Posey et al. 2010) contexts. Trust is a many-faceted topic, around which a vast literature has developed. As such, it is beyond the scope of this chapter to provide detailed treatment of the topic. We will thus briefly summarize the trust literature, particularly with respect to the interrelationships between trust and the privacy and security concepts.

McKnight et al. (2002), building on earlier work in off-line contexts (Mayer et al. 1995; McKnight et al. 1998), proposed the most popular framework for online trust formation. This model proposes that trusting beliefs about an entity's benevolence, integrity, and competence will predict the extent to which a user will be willing to transact with the entity. The recipient of trust in the majority of prior research is an e-commerce company (e.g., Pavlou and Gefen 2004), but a growing body of research investigates trust from other perspectives such as social media (Lankton and McKnight 2012), productivity software (Lankton and McKnight 2011; McKnight et al. 2011), and knowledge management systems (Thatcher et al. 2011).

Trust has been shown to be an important part of our understanding of privacy and security in online settings. Trust has been shown to predict feelings of privacy (Belanger et al. 2002), but has more often been modeled as an outcome of privacy (Chellappa and Sin 2005; Malhotra et al. 2004a), wherein a reduction of privacy concerns has been associated with higher levels of trust. Schoenbachler and Gordon (2002) showed that when consumers trust companies, they show lower concern for privacy and are more willing to provide personal information (cf. Smith et al. 2011).

55.3.1.4 Distrust

A concept that is related to but distinct from trust is distrust. Rather than assuming trust and distrust to be two extremes on a singular continuum (Rotter 1980), a mounting body of research is finding that the thought patterns underlying trust and distrust are distinct (Dimoka 2010; McKnight and Choudhury 2006). Trust tends to build slowly, with organizations and online services expending great effort to engender trust among their users (Kim and Benbasat 2003). When trust is violated, however, it is "shattered, and it is replaced with a totally different mind-set, what [we call] distrust" (Gefen et al. 2008, p. 278). Research on distrust in the context of privacy and security remains sparse, with the literature firmly focused on the relationships with trust. As with the e-commerce literature, however, differentiating between trust and distrust in the context of privacy and security can yield more valuable and unique understanding than a focus on trust alone can afford (Gefen et al. 2008).

55.3.2 Theories about Compliance Behaviors

Security compliance behavior has been a popular topic in the IS literature, particularly in the last decade. Compliance research generally deals with factors that predict end-user compliance with organizational privacy and security policies (e.g., Bulgurcu et al. 2010), but has also been examined in home security settings, which impact one's exposure to privacy issues (Anderson and Agarwal 2010). A number of theoretical perspectives have been leveraged to explain compliance behavior. We will address each in turn.

55.3.2.1 Protection-Motivation Theory/Health Belief Model

Researchers have adapted the popular protection-motivation theory (PMT; Rogers 1983) to explain why users adopt secure behavior. Closely related are the health belief model (Rosenstock 1966) and the technology threat avoidance theory (Liang and Xue 2010), the latter of which was recently developed in the IS literature as a partial extension of PMT. These theories treat security threats as hazards about which individuals make judgments regarding such factors as threat severity, perceived vulnerability, the efficacy of suggested protections, or the ability of the individual to carry out those protections. Secure behavior is thus treated similar to healthy eating or exercise habits, with individuals varying in their respective judgments of how dangerous security threats are or how vulnerable they are to being compromised in some way. These theories have been used extensively in the IS security compliance literature, in some cases directly (e.g., Herath and Rao 2009b; Johnston and Warkentin 2010; Lee and Larsen 2009; Ng et al. 2009) and in others less as a framework and more as support for individual hypotheses (e.g., Bulgurcu et al. 2010; Pahnila et al. 2007).

55.3.2.2 Deterrence Theory

A large body of IS literature has investigated the effects of punishments or sanctions in motivating individuals to adhere to organizational security policies and behave securely. The facets of sanctions that have generally been explored include severity (how harsh the punishment will be) and certainty (the perceived probability that punishment will be given) (e.g., Straub 1990). Deterrents have been found to be effective in minimizing security violations in organizational (D'Arcy et al. 2009; Harrington 1996; Herath and Rao 2009a; Kankanhalli et al. 2003; Pahnila et al. 2007) and other (Straub and Welke 1998) settings.

55.3.2.3 Neutralization/Rational Choice

Recent expansion beyond the deterrence literature has introduced new perspectives to the issues associated with end-user behavior. One such perspective acknowledges that deterrence mechanisms are effective in many contexts, but that users will occasionally rationalize or neutralize their insecure behavior even in the presence of imposed sanctions (Siponen and Vance 2010), or that users deliberately choose

to act insecurely after weighing the costs of following security policies against the benefits of disregarding them (Li et al. 2010). These perspectives have been validated empirically, and they offer a fresh understanding of the compliance issues that complement the findings regarding the effectiveness of deterrence mechanisms.

55.3.2.4 Theory of Planned Behavior

Several frameworks have been proposed in the IS literature that attempt to frame users' intentions according to the theory of planned behavior (TPB; Ajzen 1991). Dinev and Hu (2007) use the TPB to explore users' intentions to adopt protective technologies. Bulgurcu et al. (2010) frame the idea of information security awareness within the TPB and theoretically justify a comprehensive framework that explains the outcomes of information security awareness and how they relate to a user's behavioral intentions regarding secure behavior.

55.3.3 Privacy Disclosure Behaviors
